Although most research has focused on negative outcomes, studies also suggests that media content may be used to foster prosocial attitudes and behaviors among young viewers, encouraging them to interact with others in friendly positive ways. A recent meta-analysis of research on the effects of *Sesame Street* coproductions in 15 non-US countries found a small but significant positive effect of exposure to the program on children's attitudes toward social out-groups, including racial, ethnic, and religious out-groups (Mares and Pan, 2013). Other research suggests that prosocial effects on young audiences are most likely to occur when programs are viewed in a classroom setting where the teacher discusses the prosocial themes and/or encourages related activities. Correlational studies, conducted in the United States and in Europe, examining the relationships between self-selected exposure to prosocial TV content at home and prosocial attitudes and behaviors have tended to find relatively small relationships or no observable relationships at all.

One explanation is that those who watch prosocial television may often watch lots of antisocial content as well, given the prevalence of physical and nonphysical aggression in TV programing. An additional explanation is that young audiences have difficulty understanding the intended lessons and elaborating on them in ways that would lead to positive changes in attitudes and/or behaviors. In one study by Narvaez and her colleagues, children and undergraduates read stories in which the main character faced a moral dilemma (e.g., whether to return extra change), and then chose which of four choices best captured the moral theme of the story. The 8-year-olds in the study chose the right answer only 11% of the time and 10-year-olds only made the correct choice 45% of the time, compared with 91% for the undergraduates. Similar findings emerge in studies of children's comprehension of moral themes in TV or films.

Given these findings, it is not surprising that the most successful interventions involve strategies to lighten children's cognitive load and help them elaborate on the themes. For example, Friedrich and Stein (1973) found no effects of *Mister Rogers' Neighborhood* (a live action program emphasizing friendly interactions) when preschool-aged children watched the program at home. In contrast, there were significant changes among children who watched 12 episodes of *Mister Rogers' Neighborhood* over 4 weeks in preschool, accompanied by related activities. They persisted longer at tasks, were more likely to obey rules, and were more likely to delay gratification without protest, than those who watched other programs.

Effects of Media Use on Children's Health

One relevant theoretical perspective is the Integrated Model of Behavioral Prediction (Fishbein and Ajzen, 2010) which was previously known as the theory of reasoned action. This account proposes that the best predictors of behavior (e.g., smoking, sexual initiation) are the individual's behavioral intentions, and that these in turn are derived from the individual's attitudes toward the behavior, perceived social norms, and self-efficacy about the behavior. Media depictions may help shape all three of these constructs. Indeed, tests of this and related theoretical accounts show that media use is a contributing factor in a number of problematic health outcomes including early initiation of tobacco use, alcohol consumption, and sexual activity. However, the issue that has garnered most attention with regard to young children (rather than adolescents) is the role of media exposure in contributing to children's chances of becoming overweight or obese, particularly as global rates of childhood obesity have been rising.

Media Use and Children's Weight

A study of television advertisements from 23 countries in Europe and Asia found that foods advertised to children were low in nutritional value (e.g., sugary cereals, fast food, candy, snacks, and soft drinks). Similar findings have been reported in the United States. Food products are also advertised in TV programs and movies via product placement, and on websites targeting children that feature product-centered games, known as advergames. As with other forms of advertising, researchers have found that advergames primarily focus on foods that are high in sugar and fat.

Research suggests two primary ways in which media use may contribute to overeating and poor nutritional choices. First, studies indicate that children who are exposed to food advertising are more likely to prefer, request, and choose the advertised (less healthy) foods. Second, children are more likely to snack during and after television use. A third, hypothesized possibility is that media use may displace physical activity. However, studies consistently fail to support this hypothesis (see Marshall et al., 2004, for a meta-analysis).

One line of research has examined whether video games (such as those that involve dancing or simulate sports) may help children become more physically active and maintain a healthy weight. Thus far the research evidence is mixed. However, a study conducted by Maddison et al. (2011) in New Zealand found that using active video games over 6 months had a small but positive impact on body fat and body mass index in overweight and obese children as compared with a control group.

Media Use and Children's Body Image Concerns

Magazine, film, and television content all present images of thin-ideal bodies – even a content analysis of cartoons found that thin characters were associated with more positive traits

than overweight characters (Klein and Shiffman, 2005). Despite the evidence that media use is implicated in rates of childhood obesity, there is also some evidence that media use may contribute to disordered body image and eating, even in childhood. Both cross-sectional and longitudinal research with elementary and middle-school children in the United States has found relationships between children's television viewing and eating disorder symptomatology (e.g., Harrison and Hefner, 2006).

Mitigating Negative Effects of Exposure to Media Content

Given concerns over media effects on children, there have been various attempts to mitigate negative outcomes. At the national level, various countries such as the United States have restricted the amount of advertising during children's programing and required audiovisual separators between programs and ads. In other countries, like Sweden and Belgium, advertising during programing aimed at children aged 12 and younger is banned completely. Another strategy is to require advisories and content labels such as 'parental discretion advised' and 'PG-13: Parents Strongly Cautioned' that would help parents regulate their children's viewing. However, the results of several studies suggest that such advisories often have the unintended 'forbidden fruit' effect of making such content *more* attractive to children.

Other research (much of it conducted in the United States by Nathanson and her colleagues) has focused on the effects of caregiver coviewing, rules, and commentary about controversial media content, such as TV violence and sexual material. In some studies, children in coviewing-only or neutral-commentary conditions were no less likely to engage in aggressive play after viewing violent programing as those who heard praise for the violent actions depicted. In a correlational study, children whose parents regularly watched violent programing with them reported greater (rather than less) likelihood of using physical violence in various situations. One possible explanation is that coviewing without any overt criticism serves as a form of tacit endorsement of the content.

A second type of caregiver behavior, often labeled restrictive mediation, involves setting rules about the types or amount of content the child may watch. In various studies conducted in the United States and in Europe, parents were more likely to report using such strategies with younger children than with teens. Indeed, there is some indication that restriction is effective primarily with younger children and may cause a backlash among adolescents. Moreover, various researchers have noted the difficulty of effectively controlling children's exposure to violent media content given the prevalence and popularity of violence in all media forms.

The third strategy for mitigating negative effects is called active mediation (or instructive mediation or evaluative guidance). This approach involves making comments or asking questions that are intended to reduce negative effects. Several studies suggest that adult criticism of depicted violence may alter children's evaluations of the material or their aggressive dispositions after viewing. However, there is also some indication that the format of the commentary matters. In one study, simple, declarative statements (e.g., That's not how real people behave!) were more effective with 5- to 8-year-olds than questions (e.g., Do you think that's how real people behave?). For older children (9- to 12-year-olds) the question format was more effective than the evaluative statement, perhaps because such questions were less likely to create resentment by threatening the older child's sense of autonomy.

Conclusion

Because children are seen as vulnerable audiences, the focus of research is typically on negative outcomes. As this article indicates, such research generally yields small to moderate significant effects, sometimes enduring years later, as in the longitudinal study of media violence. Nonetheless, it is worth highlighting the evidence of educational and prosocial outcomes as well and the fact that these effects can endure for years too. Academics, producers, and policy makers should use current and future research to maximize positive outcomes and to minimize the more negative outcomes.

Media Ethics

Adam Drozdek, Duquesne University, Pittsburgh, PA, USA

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Media ethics is a branch of ethics that addresses moral issues arising in connection with the acquisition, preparation, storage, presentation, dissemination, and reception of information through the means of mass media. Mass media include print media (newspapers, magazines, and books), recordings, motion pictures, and electronic media (radio, television, and the computer). Media ethics seeks to help the media practitioners resolve various moral problems arising in all the areas of media communications: journalism, advertising, public relations, and entertainment. The media exercise a strong and complex influence upon the perception and understanding of the world by the public and, consequently, upon shaping the personality of each individual and the interactions of individuals with one another. News and reportage, commercials and advertisements, soap operas, and films – all exert in the long run more or less subtle influence on people's views, choices, and behavior. Because of the ubiquity of the media and their growing presence, the ethical problems that the media practitioners face become increasingly important. The number of publications and conferences on media indicates that among the issues that concern the media people and the public the most important are truth in the media (objectivity and fairness), freedom and responsibility (self-regulatory mechanisms), privacy, and the quality of the media content (violence and pornography).

Media ethics is a branch of applied ethics that addresses moral issues arising in connection with the obtaining, preparation, storage, presentation, dissemination, and reception of information through the means of mass media. Mass media include print media (newspapers, magazines, and books), recordings, motion pictures, and electronic media (radio, television, and the computer); that is, media used to deliver messages to mass audiences through mass distribution of information. Media ethics seeks to help the media practitioners resolve various moral problems arising in all the areas of media communications: journalism, advertising, public relations (PR), and entertainment. It assesses media performance, evaluates standards that guide media practice, and defines best practices.

The media exercise a strong and complex influence upon the perception and understanding of the world by the public and, consequently, upon shaping the personality of each individual and the interactions of individuals with one another. News and reportage, commercials and advertisements, soap operas, and films – all exert in the long run more or less subtle influence on people's views, choices, and behavior. Because of the ubiquity of the media and their growing presence, the ethical problems that the media practitioners face become increasingly important.

There are a number of issues discussed in media ethics that include the truth and consistency of information, fairness, transparency, open access, objectivity, honesty, respect, and tolerance. However, the importance of these issues depends on the function and nature of the media. For example, the problem of objectivity is far more important in journalism than in entertainment or advertisement; moreover, the problem of objectivity is much more affected by the visual media than by print media. Media ethics has strong ties to communication ethics; however, media communication is always mediated, whereby it often becomes a one-way communication with no direct interaction, so that recipients frequently have no control over the type and quality of information they receive through the media. This raises the ethical problem of weighing the self-interests of those who control media against the public interest.

Truth and Objectivity

Traditionally, discussion concerning media ethics concentrated around journalistic ethics for which the problem of truth is of critical importance. Incidentally, the concern with truth along with other reasons were used to consider journalistic ethics as distinct from media ethics (Czarnecki, 2007) and even to propose replacing journalistic ethics with the ethics of individual journalists (Pleszczyński, 2007).

There are two reasons for the importance of truth. First, the media are the primary source of information in a democracy and reliable information is indispensable for a genuine democratic political system. The government must be accountable to the people it represents, and one means of ensuring this is access to information related to governmental policies and informed discussion about government. For this reason, the press is often viewed as the fourth estate that monitors the actions of the three governmental estates: the legislature, executive, and judiciary (Thomas B. Macaulay's concept). Second, the use of inaccurate information contributes to a decline in the autonomy of the individual. Deception is an exercise of self-interest; it makes making choices harder and undermines human freedom.

One facet of truth in journalism is objectivity; that is, the commitment to impartiality, to reflect the world as it is, without any bias or distortion. The journalist should be a neutral, detached observer who reports facts free from personal opinion. There are aspects of each event that are independent of the convictions of reporters. News reports attempt to capture the essence of an event and its underlying causes, and locate the event in a social, historical, and political context. However, perfect objectivity is impossible to achieve. First, there is a problem of selection. News is not just reporting

what recently happened; otherwise the most trivial events would qualify as news. It is the selection of the news based on its importance for the community as reinforced by showing these events in a larger context. The news is, implicitly or explicitly, always contextualized, presented in a particular cultural framework and social perspective. Drug trafficking can be presented as an understandable way to fight poverty, as a means of providing money to buy weapons to fight for a certain cause, or as an inexcusable way of enrichment at the cost of victims' health. The mere choice of terminology can reflect one's opinions; one warring party in a certain conflict can be called soldiers, warriors, combatants, insurgents, fighters, militants, partisans, or regarded as terrorists, guerrilla, rebels, mutineers, renegades, ragtag mob. Also, what is news depends very much on where the reporters and cameras are. In the television era, reporters are influenced by the existence of good pictures and this, in turn, determines how much time is assigned to a story.

Second, journalism striving for objectivity relies on an unrealistic view of the separation of facts and values. Perfect detachment and neutrality becomes an unreachable goal, i.e., reporting facts only ('just the facts') without any personal bias. For this reason, fairness usually becomes the goal as the best approximation of objectivity. Fairness, or balance, is evenhandedness in the treatment of a presented issue; it is the shedding of light on an issue from different angles. Its opposite, unfairness or bias, often means the misleading slanting of news; because it conflicts with the central journalistic duty to inform the public, bias should be avoided. Bias can be the result of faulty thinking (giving too much weight to eyewitness testimonies which are never purely objective; looking for confirmation and not falsification of a view; using unrepresentative samples; committing the *post hoc ergo propter hoc* error), the way of presenting the material (presenting news out of context; using emotionally charged language; focusing on the negative; using close-ups rather than medium-long shots), or the nature of the organization (insufficient time allotted for news presentation). However, it frequently turns out that avoiding bias, presenting material in the most nonpartisan way possible, is simply good for business and extends the scope of viewership or readership, since partisan programs and papers appeal almost exclusively to those sharing the same views. On the other hand, partisan publications, editorials, and opinion columns are expected to be partisan. Frequently, investigative journalists or activist journalists related to some social causes are committed to certain issues and are thus biased. However, this should not excuse them from basing their opinions on verified information, confirmed facts, and a reasoned presentation of their opinions.

Although perfect impartiality is unattainable, making explicit journalists' own prejudices and assumptions can bring them closer to the truth. If journalism did not make seeking the truth untainted by subjectivity its goal, it would severely undermine its credibility and usefulness. By assuming, after the postmodernist thinkers, that truth is just a social construct, the borderline between fact and fiction is blurred, whereby no news could be trusted.

This leads to pragmatic objectivity in which the interpretation of facts is included in reporting; however, interpretations should be tested by the best available journalistic standards (Ward, 2004).

It is often stressed that in the interest of objectivity, journalists should avoid, if possible, conflicts of interest and commitment. Not infrequently, story sources want to receive positive coverage and attempt to influence journalists through gifts, free tickets to events to be reviewed, free travel, etc. Some codes of ethics explicitly prohibit receiving such favors, but for financially struggling organizations such opportunities can be hard to pass over. Also, there may be a conflict of interest when journalists are members of, or sit on the boards of, organizations they cover. Sometimes even the appearance of such a conflict can be as damaging to the credibility of the media outlets as the conflict itself. However, if a conflict cannot be avoided, it should be acknowledged to the public.

The position of truth in the context of advertising is different to that in journalism. The role of advertising is to persuade people to do something: in commercial advertising, to buy a product, or, in political advertising, to accept a person or views. This requires the stressing of the strong points of the product and omitting the weaknesses. Because the only goal of advertisement is to promote a product or idea, it is one-sided and should not be expected to be balanced and complete. The public must be aware of this and treat the advertising accordingly: *caveat emptor*. Also, advertising is a persuasive, not rational, communication. As such, it wants to catch potential client's attention, and is not primarily concerned with the product's quality. But this does not mean that truth is irrelevant for advertising. Advertising should not be deceptive by suggesting nonexisting qualities of a product; it should avoid deceptive means, such as using staged testimonials. Furthermore, an advertisement should be clearly distinguished from a detached presentation of facts. This distinction is violated in infomercials where advertisement is presented as facts so that it may not be clear to the viewer or listener that an infomercial is really a persuasion method presented in a disguised way as an objective fact.

Similar statements can be made about PR, which is the management of communication between organizations and the public; frequently, this is done not only to provide the public with information about organizations, but also to create a positive public image of a particular organization, group, party, or person, often to gain public support to champion a cause. This is done by controlling the flow of information that is presented to the public. Persuading the public, winning it over to a cause, not truthfulness, is the goal. However, when PR managers resort to the use of misleading or manufactured information, their pronouncements can lose credibility in the eyes of the public and have the effect opposite to what was intended. Therefore, although bias is written into the essence of PR, it has to have a strong component of veracity, accuracy, and verifiability of information.

This element is particularly important in political advertising. Politicians must win public support to win an election, so they must have legitimacy obtained by favorable media visibility which stresses the positive and downplays the negative aspects of the politician's views and activity. This often means diverting the public's attention from important political and economic issues to what plays well in the media, particularly on television: polished demeanor, good looks, witty

ripostes. It is claimed that the voters are more interested in the trustworthiness of politicians than in their particular promises. Realization of this problem leads the politicians and their PR advisors to project the best image of these politicians through the media, to shape in public opinion an image of their great personality and character. For this reason, political PR advisors and consultants become increasingly important on the political scene.

Freedom and Responsibility

The freedom to publish opinions is defended with the argument that it is necessary for democracy, and that the discovery of the truth requires a free marketplace of ideas. However, others say, the powerful dominate the media, and consequently the competition of ideas is not genuine because the access to the media is unequal. Also, an argument is used that free speech fosters individual autonomy and development, but, on the other hand, it may encourage hate speech and obscenity.

Unqualified free speech, even in democratic society, is unattainable and it is legally restrained, e.g., in the interest of national security and public safety. There remains a problem of defining the situation when national security is endangered. It is sometimes maintained that the United States lost the war in Vietnam because the media coverage largely undermined the image of the military. Hence, media coverage of the British military operations in the Falklands (1982) and the United States operation in Iraq (1991) was restricted much more severely than necessary.

Most media practitioners realize that – notwithstanding legal issues – free speech must be qualified with responsibility. Journalists in a democracy have a responsibility to foster pluralism and diversity of political debate, and to refrain from perpetuating myths about different social groups. Also, the media must take into account the consequences of their actions. For instance, reporters can sometimes anticipate that their approach to news gathering may induce antisocial behavior: the camera can turn a demonstration into a riot, and a live coverage of a hijacking, which gives the hijackers free publicity, makes hard the release of the hostages. When their stories bring some harm, journalists defend themselves by saying that they just report a story. But news organizations are very willing to take the credit for positive consequences. News is created by journalists, so they need to be sensitive to possible influences their news may have. They need to take into account who may be harmed by their actions. This is particularly important in the context of citizens' privacy (*see* Privacy of Individuals in Social Research: Confidentiality).

Privacy

Journalists justify breaching someone's privacy by saying that the public has the right to know. This is an important argument, because it implies that the media are obligated to publicize some reports, whereas the freedom of the press merely permits such publicizing. However, the argument leaves unspecified what it is that the public has the right to know. Although the media, journalism in particular, ought to act in the public interest, it does not mean that they are obligated to fully satisfy the public's interest. Public interest is not tantamount to mere curiosity. The critics indicate that the media much too often publicize information to satisfy the public's curiosity, but refrain from publishing revelations about the media themselves; journalists routinely avoid stories that put other journalists in a negative light (Hausman, 1992).

The problem of privacy violation is particularly acute in the case of public figures. It is often said that public figures relinquish their right to privacy by the very fact that they become public figures; the loss of privacy is a price for being famous and thereby for high social status, wealth, power, etc. For this reason, all details of private lives of public figures can be published. It is claimed that in the case of politicians such details are important, because their personal qualities can interfere with their public duties and affect their decision making, especially under pressure. Also, the character of the people associated with a politician influences the politician's priorities and decisions. People elect a whole person, not only a public side; consequently, they should know about the private side as well. Hence, notwithstanding the motives of the media, they are acting on the public's behalf as a watchdog of the political arena, and, therefore, they have the right and responsibility to know the facts concerning people who shape political and economic policies of the country. In particular, the media should expose the hypocrisy of politicians who publicize goals and policies that are at variance with their own life. However, others say, in line with La Rochefoucauld's maxim, that hypocrisy is the homage which vice pays to virtue, and, hence, if positive policies are enacted in spite of violation of them by the enactors, so much the better for the policies. For this reason, a hasty exposure of politicians' vices can be counterproductive because it may lead to the demise of the politicians and, consequently, to the demise of their positive and desirable policies. Besides, an invasion of privacy discourages many people from entering an election race, which is detrimental to the democratic process. It is also said that to maintain their mental health, public persons should have time off from the sight of the public.

Privacy is violated by undercover investigation and the use of long-range cameras, electronic eavesdropping devices, or surreptitious recording. The use of such means is often justified as indispensable in the investigation of crime and corruption, public health dangers, and safety negligence because it may be the only available means to unearth the story, and it may contribute to greater objectivity of the story. However, the critics maintain that the use of such means may lead to a general erosion of trust, and discussion of the news obtained by questionable methods often focuses on these methods rather than on the news itself.

Self-Regulatory Mechanisms

The media recognize that some self-regulation is necessary to avoid an erosion of confidence and public demand for governmental regulation. Self-regulation aims at establishing ethical guidelines for professionals to properly address legitimate concerns, respond to complaints, and solve problems. There are several mechanisms used to develop and maintain responsibility of the media.

Codes of ethics mark the stage of maturity of a profession; they are an indication of good faith and thereby project a positive image of an organization or company and enhance its credibility. They also articulate values of this profession, provide a framework for self-regulation, and can help to define and direct the work of professionals by providing ethically relevant framework and setting moral standards. On the other hand, codes of ethics are not infrequently too general, vague, and lack specific guidance for particular situations; also, they often leave open the problem of implementing the enforcement mechanism. However, such codes are generally useful as an educational tool, particularly for novices in the particular profession. They can be used as a defense against doing something that violates them; they can be used by the public to see whether ethical standards are followed by professionals; also, they force professionals to reflect on their obligations when formulating the code.

Another mechanism is internal criticism by a neutral arbitrator within the organization to investigate and to respond to complaints – an ombudsman (Swedish for 'deputy') who can increase an organization's credibility, because the existence of an in-house critic signals to the public its sensitivity to public opinion and its willingness to modify the organization's practices. However, only a small percentage of media organizations have ombudsmen (cf The Organization of News Ombudsmen and its site, newsombudsmen.org).

Moreover, press councils are formed, with variable success, to debate complaints against the press (e.g., British Press Council since 1953, Der Deutsche Presserat since 1956 in Germany, National News Council in the United States in 1973–84; for a list of an ever-growing number of national and local press councils, see www.media-accountability.org and wanewscouncil.org). They are primarily composed of media professionals and their primary task is to deal with complaints concerning the maintenance of ethical standards of the profession.

Finally, education offered in classes on journalism ethics, conferences, meetings, and seminars explores issues of media ethics. This education is important in at least two respects. Not all journalists have majored in journalism and thus they may not have taken classes in professional ethics. Moreover, focusing on ethical issues in some meetings and seminars indicates that the ethical side of exercising journalistic profession is important for a particular media organization or company.

Quality of Media Content

The media practitioners frequently argue that they show and publish what the audience wants, which is determined democratically by conducting polls, and that the criticism of the media for low-quality programs is elitist. This argument is rebutted by the claim that the media respond only to the immediate interests of the public, and what goes beyond these interests is inevitably disregarded. Also, this way of determining interests has a tendency to confine them to the lowest tastes. The pursuit of higher ratings leads to trivialization and sensationalism of journalism ('yellow journalism') and entertainment. The proliferation of tabloid journalism is the result of a conviction that the media only reflect the public's tastes; interests in sensational and bizarre aspects of our culture is natural, and no harm results from satisfying them. However, it is claimed that the constant exposure to tabloid journalism diverts public attention from important social and political problems, and gives credibility to sensational aspects of human existence. Tabloid journalism has become mainstream because sensationalism is one of the most important elements shaping the news, particularly in television, which, by definition, gives rise to distortion. Visual media call attention to conflict, magnitude, the unusual, the sensational, and the spectacular. Television relies on brevity and swift transitions. Visual events (fires, crashes) gain prominent coverage on television; an explanation of a tax reform receives only a short sound bite. The public will eventually come to think that the sensational aspects are the norm.

The reliance on sensationalism is apparent in entertainment. For example, talk shows live on the voyeurism of the public and exhibitionism of the guests. The primary goal of exposing the unusual behavior or appearance of talk show guests is to entertain the public, not to help the guests. The shows break taboos, exhibit deviant behavior, and make it appear ordinary. They blur the line between private life and the public domain by moving the former into the latter with the help of willing participants who may not be entirely aware of, or simply do not care about this shift. These shows also feed on the viewers' willingness to watch others publicly reveal the most private matters even if these viewers would never make such revelations public.

Stressing the sensational manifests itself in the saturation of entertainment with violence and erotic content. Many media critics express a concern that watching violence stimulates violent behavior generally, and copying the watched behavior in particular, people who watch violence regularly become desensitized to its horror and may even develop a positive attitude to it. However, it is possible that pictures of violence increase the level of revulsion concerning its consequence, that it inhibits aggressive behavior, that is, it has a cathartic effect – Aristotle claimed that a tragedy with its depiction of 'serious actions' has a cathartic effect (*Poetics* vi).

The effect on children of watching television is probably the most researched subject today in media influence on people. Results of many research studies indicate that television, especially the depiction of violence, has a profound effect on children's behavior. This is also true for computer games, which have become increasingly saturated with violence. Also, action movies engage viewers' emotions and reduce them to primal instincts, leaving out intellect (Sloterdijk, 1993). However, some say, even granted that it may be difficult to establish empirically the existence of a causal link between viewing and future behavior, many actions of the media are predicated on the existence of such a link. For example, if there were no influence of the media on the public, no organization would invest any money for advertising. Therefore, if noncriminal behavior can be influenced, it is difficult to assume that the media have no impact on criminal behavior. Moreover, constant repetition is both a tool of education for acquiring and holding information, and of propaganda for getting across a political message. It would be remarkable if constant viewing of violence in movies or games did not have a similar effect.

The media often use rating systems to indicate the content of films and shows, but, some contend that this system is often used as an allurement rather than a warning, and the movie producers are tempted to include gratuitous violence, pornography, and profanity in their products to make them more appealing.

The media create popular culture, and in this culture they gravitate toward what is most exciting. Therefore, popularity seems to be a crucial factor in deciding the content of the media. But if popularity is a deciding factor, then there is no room for creativity and acceptance of new ideas. There is little room for real choices because the media become the subject of a form of Gresham's law which says that poor quality entertainment drives out high-quality entertainment, news, and educational programming (Fink, 1988).

The Internet

A distinctive feature of traditional media (press, movies, TV) is the rigid separation of media providers and consumers in which all control of the type and quantity of produced and transmitted information is in the hands of the providers and in which consumers are only passive spectators. The situation drastically changes in the context of the Internet where interaction of the two parties is fairly easily achievable. An online journalist can receive immediate feedback in the form of praise, criticism, correction, additional information, etc. from the reader and this feedback can very quickly appear in an online publication. Including the Internet in the picture can also make traditional media interactive. An online poll can be immediately presented on TV news; questions sent via e-mail can be instantaneously presented to a person interviewed on a TV or radio program.

In the context of such interaction, the roles of information providers and receivers can be blurred and even reversed. In traditional media, a journalist is fully in control of the information provided to the public. This may also be the case in online public/civic journalism. Frequently, however, a site mostly or entirely relies on the information that comes from the public (through regular mail, e-mail, comments posted online), and only the journalist supervising the site may decide which information to post and can also edit it to make it more readable. The journalist is still in control, but in the role of a controller, whereby, in a way, the ethical role of such a journalist-supervisor is even more pronounced than in traditional media: ethical guidelines should decide which information submitted by the public is posted and which should be rejected, if it is e.g., libelous, blasphemous, disrespectful, hurtful, or some other legitimate reason. Such a journalist may also encourage the public to provide some types of information, e.g., information that addresses public health issues (hard news) and not only where to groom a pet (soft news). In this way, civic journalism establishes very close connections between journalists and the public with the intention that the proactive role of the public can influence the political agenda of the community and thus enhance and shape democracy. However, the overarching ethical principles for journalists in the new media are very much the same as in the old: providing truthful information, promoting of the democratic process, respecting for differences, avoiding or at least minimizing harm, and the need for verification of information, even if methods may vary (prepublication verification is required by traditional media, online journalism leans toward postpublication verification).

Another distinctive feature of traditional media is the rigid separation between different types of media. With the Internet, a unification of media is possible. The Internet allows for an easy way of mixing the media. A text can be amplified by still images, audio and video clips, accessible through links added to the text. Links can also lead to other sites and other Web pages with relevant information. Moreover, since TV transmits programs digitally, they can easily be viewed on a laptop, tablet, or even a cell/mobile phone. Newspapers and scientific journals have increasingly made digital version accessible in the cyberspace, and thus the line between newspaper and TV becomes blurred to the point that the prospect of media convergence arises in which the capabilities of various media are merged into one supermedium (cf Phadke, 2008).

There is much more information readily available on the Internet than before the Internet era. This may make abiding to ethical principles more difficult. Because of the sheer amount of information, checking its validity and confirming facts can become an onerous and time-consuming task. Because of time pressure, particularly in cyberspace, some information can be presented without sufficient verification, possibly with a warning, so that the audience should decide how credible the information is. In this, responsibility for the credibility of information is, at least partially, shifted to the audience.

Media User Ethics

Enforcing the ethical standards in the international context of one large digital supermedium is well-nigh impossible, and thus the public should be much more aware of the potential dangers posed by this medium than before. Therefore, the following guidelines have been proposed to direct the consumer in its use. The consumer should (1) be alert and discriminating; (2) oppose censorship; (3) not unduly interfere with editorial independence; (4) guard against sexist and racist stereotyping; (5) look for alternative sources of information; (6) ask for a pluralist supply of information; (7) protect one's own privacy; (8) be a reliable source of information; (9) avoid participation in for-profit journalism; (10) demand accountability of the media (Hamelink, 1995). Such obligations concern the public as participants of mediated communication process in at least three respects: civic duty; economizing one's own schedule; and responsibility for the upbringing of children (Funiok, 2007). This calls for an active participation of the public in shaping the media so that they deliver their content in the way that enhances the wholesomeness of the social environment. Receiving this content is as important as not receiving it, which cuts to the time spent on being a participant of the media communication (watching TV or maintaining one's blog). Finally, parents are responsible for protecting children from potentially harmful yet easily accessible media content.

Media Events

Abstract

'Media events' is a concept developed in communication and media studies literature in the 1980s and 1990s, primarily by Daniel Dayan, Elihu Katz, and their associates. It describes large, preplanned social or political events, usually of ceremonial form, often sponsored by the state or other traditional institutions, broadcast live on television and dominating other media, and attracting unusually large and attentive audiences. Inaugurations, state funerals, royal ceremonies, diplomatic visits, and the Olympic Games are typical examples, usually seen as socially integrative ceremonial television. Since the first writing on the topic, other authors have challenged the possibility of ceremony and community by media as well as proposed more attention to conflictive events, social change, historical context, and the relation of these events to the conduct of social power. The recent literature has been dominated by reconceptualizations motivated by more attention to historical context, to globalism, and to the apparent dominance in recent years of conflict, crisis, war, and international terrorism over integration, ceremony, and celebration.

Media events, as the term is used here, are large, planned events that interrupt normal media schedules and audience activities, obtaining special coverage and special attention. State funerals, royal weddings, diplomatic visits, legislative hearings, political inaugurals, and the Olympic Games are representative examples. In these cases an agency, independent of the media, sponsors an event, with a claim to historical importance. The media validate that claim by interrupting their normal schedules for live coverage. The audience delivers the final validation by granting the media event their special attention. When successful, such events have an integrating effect on societies, working as secular ritual. The media event is not only media coverage of something important, but a new social form in which the original event, the media coverage, and the activities of the audience at home unite in a form of dispersed ceremony. This raises a host of questions for analysts about the power of communication, the possibilities for participation at a distance, and the potential misuse of ceremonial forms and audiences, as well as inspiring criticism of the role these events play in reinforcing established institutions and authorities. These questions and concerns have produced vigorous debate and a literature full of proposals for reconceptualization and alternative perspectives on media events and their social roles.

The Paradigmatic Conception

The term 'media event,' of course, is used in a variety of ways. The paradigmatic conception of media events addressed here was developed by Elihu Katz, Daniel Dayan, and their collaborators and students in the 1980s and that early work appeared in a series of articles and dissertations. The concept received its most coherent, complete, and influential presentation in Dayan and Katz's (1992) *Media Events: The Live Broadcasting of History*. Following that work, 'media event' has become a technical term in communication and media theory, to describe what is essentially ritualized, ceremonial television: an interruption of the normal routine for a live broadcast from a remote location of a preplanned event organized independently of the media; the tone of the broadcast is more serious, ceremonial, or even reverential than normal, it attracts unusually large and attentive audiences, and it often has serious political and social consequences. The concept has been used in studies of a wide range of phenomena, from formal state events to media award shows to cult films and fan communities to disaster news and terrorism, as well as generating extensive and vigorous theoretical debate (e.g., Liebes and Curran, 1998; Couldry et al., 2010).

The early studies focused on Sadat's first trip to Jerusalem, the early travels of Pope John Paul II, the wedding of Prince Charles and Lady Diana, the televised Olympic Games, and historic events like the astronauts' walk on the moon and the funeral of President Kennedy. Examples from recent years include the first inauguration of President Obama, the funeral of Edward Kennedy, the Opening Ceremonies of the Chinese Olympic Games, the Royal Wedding of Prince William and Catherine Middleton, and the Diamond Jubilee of the Queen of England. These examples, with the explicit and intended centrality of ceremonial form and attitude, illustrate the paradigmatic form of the media event as an example of ritual communication and an updating of Durkheim's (1912/1995) analysis of the role of ritual and ceremony in modern society.

One of the early approaches to the study of media events melded Weber's method of ideal-type sociology with genre theory. Media events were seen as tending toward three generic forms: contest, conquest, and coronation, corresponding with Weber's three forms of rational, charismatic, and traditional authority (Katz and Dayan, 1986). Contests are modernist; they celebrate fair play, the empirical measure of results, and rational decision. Conquests, like Sadat's trip to Jerusalem, celebrate the heroic individual. Coronations, like inaugurations or royal events, celebrate tradition and continuity. This formula has been a focus of scholarly attention with repeated proposals to add conflict as a fourth term and other analyses amending and elaborating the three original terms. Dayan and Katz (1992) also explored the possibility that all ceremonial media events contain at least rudimentary elements of all three forms with one or another being elaborated in a given instance.

 http://dx.doi.org/10.1016/B978-0-08-097086-8.95046-3

This is clear in the Olympic Games, for example, where the sports themselves are rationalist contests, the media coverage features conquest stories of charismatic heroes, and the whole event is opened, closed, and punctuated by carefully governed traditional ceremonies.

Other uses of the term media event deserve attention and help illustrate some of the key issues of concern and debate in the scholarly literature. Among the professionals who coordinate events for media coverage, a media event is anything arranged for the purposes of media coverage, such as a press conference, public appearance, or photo opportunity. These events are, by definition, designed to achieve the social purposes of their subjects or sponsors. Given the predominant role of the for-hire communication professional vis-à-vis the journalist working, at least in principle, under the ethical ideal of representing the public interest, many of these events are contrived, the journalists who cover them feel manipulated, and so will much of the audience.

Already, early in the television age, long before either the media or their audiences had grown so cynical as in the present, Daniel Boorstin (1961) had coined the term pseudo-event for phenomena that have no stature independent of media coverage. The press conference, the celebrity interview, the news release, the photo appearance, and so on would not exist were it not for the chance of media coverage, and usually have no substantive social consequences unless they are covered. To the extent the media and the public are giving their attention to pseudo-events, they are presumably distracted from more real or more consequential events elsewhere. This is an important critique of media performance and it touches on fundamental philosophical issues for any communication theory as well. Boorstin and the many other critics after him using arguments of this form distinguish, at least implicitly, between symbolic things, or communicative things, and things that would exist independent of communication. They then privilege the noncommunicative things, at least implicitly, in preferring communication to be about that which would exist independently. This misrecognizes and undervalues the importance of communication itself as an event of the world and especially the performative capacity of communication to bring about effects and consequences in the world (Peters and Rothenbuhler, 1989). In such familiar rituals as the wedding ceremony or the oath of office, for example, it is the performance of signs and symbols, the communication as such, that produces the effects of the ritual, and some of this capacity inheres in communication of all types and contexts (Carey, 1988; Rothenbuhler, 1998, 2006a).

We will return to these issues below, but first let us consider what phenomena of the observable world are captured by the paradigmatic conception of a ceremonial media event. From Boorstin's own era, the live television broadcast of the funeral of President John F. Kennedy and the surrounding events attracted an extraordinary audience. For extended periods of time it appears that a majority of all Americans were watching and hearing the same events at the same time on television. These were ceremonial events that followed a social crisis and preceded a return to normality. Research conducted at the time showed that huge numbers of people were attending to the television coverage, reporting that they thought it important, and rearranging their schedules to watch it, often in groups of family and friends. Many people also reported symptoms of stress, anxiety, and uncertainty in the days following the assassination, which receded to normal levels in the days and weeks following the televised funeral (Greenberg and Parker, 1965).

Similar phenomena were found in attendance to television coverage following the terrorist attacks on 11 September 2001 (Noll, 2003). Those events and their coverage lacked a central ceremony in any classic sense, of course, they were not preplanned, institutionally sponsored ceremonial media events in the standard form, nevertheless, they were replete with quasi-religious and ceremonial symbols and forms (Rothenbuhler, 2005). The crisis event was an anticeremonial, antisocial interruption of everyday life and was compensated for, and recovered from, via a counterbalancing extra attention to symbol and ceremony in the media coverage following the attack, from that first morning right on through the annual anniversary ceremonies (Rothenbuhler, 2006b).

To choose another example, seemingly from the opposite end of the spectrum of seriousness, every four years the broadcasting media interrupt their normal schedules for special coverage of the Olympic Games. This is a large, regularly reoccurring event, organized by agencies officially independent of the media. Much of the coverage is live and both broadcasters and audiences betray an ethical preference, in criticizing edited and tape-delayed coverage and packaged programming segments. Media agents emphasize the importance of the games within and beyond sports; they make frequent historical comparisons and provide coverage of preceding and concurrent social, political, and cultural events. The games attract an audience that is unusually large, heterogeneous, and attentive. They are more likely than normal television audience members to be in groups, to be eating and drinking, to have planned their viewing ahead of time, to have rearranged their schedule to accommodate the viewing, and to have visitors from outside the home (e.g., Rothenbuhler, 1988).

Therefore, although originating in the world of sports and games rather than politics, work, religion, or life and death, the broadcast Olympic Games also show evidence of seriousness. Although they have much of the pseudo-event about them – so much of the television presentation is designed only for presentation, or repackaged so radically for coverage – along with the many other examples of media events they illustrate another classic dictum of social analysis: If people define things as real, they will be real in their consequences.

Many of the events selected for case studies in this literature have continued to be remembered as peak moments in television and media history. In examples like the broadcasts of the funeral of President Kennedy, Anwar Sadat's first trip to Jerusalem, the early trips of Pope John Paul II, selected Senate hearings, the first inaugural of President Obama, the television coverage itself became ceremonial and the audience was recruited into a sense of participation at a distance. In that case the activities on the scene, the coverage, and the audience activities at home or wherever viewed, together constituted a new event, a media event that was constructed as and functioned as a ritual in mediated communication. As ritual communication, it had the performative capacity to create its own social consequences, to produce the realities it described.

Theoretical Implications and Conceptual Tensions

If the media event constitutes a ritual and it is not a false one, those facts have major implications for social theory more broadly – and the idea was not received without debate. Other strains of conceptual tension followed from a general suspicion of ritual and representation, the selection of events for study, an interest in applying the idea to examples of conflict and social change, and a concern for the influence, if not the power, of the media. We will consider each of these issues in turn.

The face-to-face context is conventionally presumed to be necessary for ritual and ceremony; such communicative products as television or newspaper coverage, commemorative art, or memoirs are considered by-products. The audience on the scene may be considered primary, and may participate in the ceremony as congregation or witness, while media audiences would be considered secondary spectators. In the media event, though, the happenings in the face-to-face context are only a part of the event, no more important than the coverage and the activities of the at-home audience. The audience on the scene of a state funeral media event, for example, plays a role on the stage of the event, while the audience at home becomes the official audience, or even a kind of dispersed congregation (Dayan et al., 1984; Katz and Dayan, 1985).

MacAloon (1984) denied this was possible. While analyzing the role of ritual in pulling live spectators at the Olympic Games into a communal order, he asserted that ritual and community by television were impossible. While the power of symbols is widely recognized and the capacity of ritual to create social realities is accepted by scholars, as well as anyone who has ever planned a wedding, the idea that television could be the medium of that power is discomfiting. Television is, after all, a technology of spectatorship and a medium of entertainment, on the one hand, and the rational, modernist principles of journalism on the other. In the one case it is not about reality, nor serious, and in the other it should be objectively reporting rather than creating.

Compare the media event with a broadcast religious ritual. The broadcast would not appear to be the ritual, any more than a painting of a scene could be mistaken for the scene. Yet, observation consistently shows that for the faithful the broadcast coverage can function as participation in the ritual and have many of the same effects that physical participation would have. Who is to tell the faithful that television viewing does not count, if their belief and behavior confirms that it is special in their experience, and if religious leaders encourage such behavior and confirm their feelings? While the Pope himself has on occasion blessed the television audience, research shows that both commercial entertainment dramas devoted to religious subjects and apparently exploitative, money-raising television preachers also inspire genuine faith and devotional activity in some of their audience. Who, watching television on the morning of 11 September 2001 did not feel that they had witnessed the collapse of the Twin Towers? Much of the television audience of Lady Diana's funeral also like the audience for President Kennedy's funeral 35 years earlier, and surely many in the smaller audience for Ted Kennedy's funeral more recently, acted as if and felt themselves to be participating in the mourning. Of course the audience at home does not get wet if it rains, but that may not matter for meanings and effects that can work through the dramatic performances of mediated communication. The implication is that the media event is a new form for the ritual and ceremony that Durkheim (1912/1995) argued provides the quasi-religious foundations of society.

The ceremonial aspect of media events and the social consequences of its ritual power are quite distinct from what is normally expected of news coverage. There is reason for concern that it could be misused, and that the attitudes and behaviors appropriate to ritual and ceremony might spread to other domains where they would not be appropriate. Becker (1995), Chaney (1983, 1986), Liebes (1998), and others have pointed to the dangers of ritualizing media coverage. Politicians will prefer ceremonial treatment as it implies their actions are that much more important, while giving journalists and the public reason to regard them reverentially rather than suspiciously. From the media point of view, interrupting normal programming for special coverage can give the audience special reason to watch, it can enhance the status of the journalists and their channel, and the excitement can be its own reward. There are pressures, then, to ritualize even small events such as the opening of a press conference. Simultaneously, we can expect media organizations to be on the lookout for any event large enough to warrant special coverage and the claim to being a participant in historic events. Such tendencies can short-circuit rational consideration and democratic process, and diffuse the resource of audience attention.

Consider also the performative power of the ritualized media event. If successful media events can produce social integration and loyalty to ideals, symbols, and traditions, any critical consideration of the desirability of that outcome is obviated. Media events are, by definition, sponsored by authorities, central powers, and traditional institutions with the cooperation of the mainstream, national media, and they may in turn have the power to create more loyalty to these already powerful institutions. This has attracted considerable critical attention. Similarly, as the case studies on which this literature is built were primarily selected to illustrate these very ideas – state funerals, royal weddings, and such – there have been many attempts to broaden the concept to include more popular, less authoritative events like sports matches, televised contests, award shows, and fan-organized events, on the one hand, and to include more conflictful, unofficial, or antiauthoritarian ones on the other hand.

The study of mediatization (Lundby, 2009) also casts a new light on media events. This line of research shows how the internal forms and logics of media institutions, genres, and technologies become influential, implicitly or explicitly, in other social spheres. Politics, to take the most familiar example, has come to be shaped by and for the media, taking on many forms familiar from news, entertainment, and celebrity culture. So too has contemporary religion and education been influenced by media logics. Children's toys are increasingly designed to fit the promotional logics of television; fast food restaurants and airport waiting rooms have become media outlets, among many other examples (see Hjarvard, 2008).

These studies of mediatization raise questions about the production of media events and the influence of the needs of television on the event itself. This question had precedent in the earliest days of television and it remains a difficult one to

sort (Lang and Lang, 1952; Katz and Dayan, 2003). The small screen and domestic setting of the television, for example, produces a preference for close-ups, thus faces. The need to tell a story, the need to attract and hold attention leads to a preference for emotional reactions on those faces and narrators who speculate about feelings. If these forms are used for socially important events, it could tend to produce a personalistic, emotional understanding of society and history – not what the theory of modern democracy would prefer. In the process of producing media events, then, there may be a mediatization of the social forms of a previously independent institution; the ceremonial order may then be reshaped for television. This can be readily observed in the Olympic Games over the last 50 years and one wonders if the Queen of England's Diamond Jubilee celebrations in 2012 was not the most television-ready of them all.

The historical influence of the media on traditional rituals and ceremonies is only one side of the process. Another aspect of mediatization in relation to media events is the tendency of the media to 'eventize' everything they can. The mass media are attention machines; they are designed for attracting, holding, and aggregating attention. Media professionals, then, prefer what is special, unique, important, big, and dynamic; they will work to develop those characteristics wherever possible. In this way routine news and everyday entertainment comes to be promoted as if it were a special event worthy of interrupting the routines of our lives, like the ceremonial media event.

In addition to the theoretical questions about the possibility of mediated ceremony and participation at a distance, and concern that the power of that is ripe for misuse, concern that the ritual form of the media event is not appropriate to news coverage, on the one hand, or that too much influence would go the other way and that media would reshape the forms and processes of previously independent institutions, there was also a concern that the original work on media events was too focused on integrative events, on traditional events, and socially positive outcomes.

Some of this appeared in calls to shift attention from ceremonial television to the live broadcasting of history. The implicit tension between those orientations was displayed by the title of Dayan and Katz's book, *Media Events: The Live Broadcasting of History*, and while the consistent emphasis of the text was on the ceremonial, for some readers what was most intriguing were the examples of television and media participating in historical events and processes of social change.

Scannell (1995) criticized the book for 'historical flatness,' for lack of attention to how the past was different. He proposed that the type of events under study were already fading away and that there is "something almost nostalgic about the kinds of event which the authors take as their focus of concern" (p. 155). The aura of ceremony and the charisma of authority, he proposed, were worn away by television and the electronic media, by the constant performance and display, which teach the audience to watch as critics rather than as citizens or congregants. Nevertheless, he points out, the moments of live coverage of highly charged, real world events do produce a sense of witnessing, and it is this historically situated experience that he argues deserves more attention. He would, in other words, emphasize what the media coverage of the Kennedy assassination and the funeral have in common, as important historic events unfolding in live broadcast coverage. The more ceremonial conception of media events emphasizes the differences between the funeral, as a planned ceremonial, and the news events leading to it. One view emphasizes the flow of historic experience, the other emphasizes the forms of the communication that punctuate that experience.

The emphasis on history over ceremony draws attention more toward change and conflict than tradition and integration. Others turned the media events framework on specifically conflictive events. Carey (1998) provided an analysis of televised political rituals of degradation and excommunication. The Senate confirmation hearings for Supreme Court nominee Robert Bork – which resulted in his rejection – is his primary example. The point of Carey's analysis is to demonstrate a type of media event devoted to "ceremonies at the social level of excommunication defining the permissible range of social discourse; and, at the individual level, of status degradation marking out the consequences for transgressing this range." These are, then, ceremonies of great social importance, and serious personal consequence, taking place also, like the more integrated forms of media events, in and by media.

Liebes (1998) proposed the disaster marathon as a quasi-genre of news coverage in which some of the thinking and work routines appropriate to media events are carried over into other coverage. Liebes' concern is with open-ended, live coverage of disastrous events – terrorist bombings, airplane crashes, and so on. In such cases, media workers turn over much of their normal control of coverage to unscripted events, available spokespeople, and person-in-the-street interviews. Emotional reaction prevails over analysis, with one emotional expression feeding the next and no one being able to bring the coverage to a sensible close. Liebes worries that such live-coverage marathons can highjack a representative democratic process, as the media coverage of emotional public reactions short-circuits the deliberative process – and actually coaches the public to respond more emotionally than thoughtfully.

One of the interesting features that Liebes essays on disaster marathons, has in common with earlier writing on media and ritual, is an underlying concern that what might be appropriate for one category of social life, ritual and ceremony, is being applied to another where it is not appropriate, in news coverage and politics.

This line of analysis was developed further in a series of articles on the news coverage of the terrorist attacks on 9/11 and subsequent political and popular responses (Blondheim and Liebes, 2002, 2003; Liebes and Blondheim, 2005). The argument was that the disaster marathon form of coverage has the unintended consequence of increasing the terror, and thus the terrorists' grip on public attention and political process. Others have examined terrorism as a kind of media event (Weimann, 1987; Weimann and Winn, 1994; Nossek, 2008) and Sumiala (2013) has turned the lens on news coverage of school shootings and other violent events, as well as celebrity deaths.

Parallel to these works on conflictive and negatively charged forms of media events has been a literature proposing a critical theory approach to the topic (e.g., Couldry, 2003). From this perspective, a media event sponsored by the state or some other

powerful institution and carried by capitalist media, that succeeds in recruiting large and attentive audiences, especially when willing to suspend disbelief and grant the values, symbols, and narratives of the event their credulity, calls for critical analysis. These scholars focus on such issues as how the sponsoring institution uses the event to maintain its social power, how the media use the event to further their own interests, including cementing their position as privileged communicators providing access to the symbolic social center, and how the communicative relationship with the audience is then distorted, portraying itself as a transparent channel when it is in fact manipulation. The point of emphasis among critical scholars varies, of course. For some, the key is that media events in modern society work as Bloch (1989) said about rituals of authority in traditional societies, as a distraction from the real. Others, Couldry (2003) especially, emphasize that media events are 'constructions, not expressions' and that the sense of social order, power, importance, and connection that they convey are their own self-reinforcing creations. This performative aspect, the capacity of the media event to produce realities it purports to describe, was already inherent in the theory and attention to the construction and performance of events was a thread in the earlier literature. Nevertheless, the emphasis Couldry and others laid on the role of the media event in producing and preserving social power is distinct.

Media Events in a Multichannel, Hyperpartisan, and Globalized World

The paradigmatic ceremonial television conception of media events was developed in the 1980s and early 1990s, in a world where one or a few national networks dominated television in most countries, where national communication systems were relatively closed off to each other, when there was hope for peace between the Israelis and Palestinians, hope for consensus among the parties in the Western democracies, the Cold War had ended, and terrorism, war, and conflict did not dominate the news and political discourse as they have come to do in the years since. The much changed conditions in which we share our globally connected, contentious, and violent world, and a seeming decline in the number and importance of media events of the traditional kind, produced new critiques of the original conception and to new thinking on the part of its authors as well. As Scannell (1995) proposed, historical thinking has over taken the more formalist, theoretical focus on ceremony.

Katz and Liebes (2007) offered a major reconsideration of media events, arguing that coverage of disaster, war, and terror had coalesced into a kind of disruptive media events genre of its own that was upstaging ceremonial events, thus displacing the integrative functions they had served. They proposed that the changing technologies and organization of the media had fragmented audiences, dispersed their attention, and made live coverage of purportedly special events routine. Media audiences worldwide had grown more cynical and disenchanted, less ready for ceremony and celebration, more prepared to believe bad news than good. And the global media system allows bad news from somewhere at most any time. The result was that "marathons of terror, natural disaster, and war have become established genres of mainstream television" (p. 163). This was a move to open up the concept of media events to consideration of major news events, historical context, and change, as well as conflict. It was well received by former critics of the media events theory. Less explicitly, it was a move away from the ceremonial conception and the forms of analysis that follow from that.

Dayan too has been involved in the reconceptualization of media events, motivated explicitly by greater attention to the changing historical context. Price and Dayan's (2008) *Owning the Olympics* collects a set of studies focused on preparations for the 2008 Summer Olympics in China and its worldwide broadcast, and presented as testing and updating the media events idea in the context of a changed world. Across the chapters collected there we see the Chinese government, its journalists, and people, the International Olympic Committee, sports federations, other nations and national media, journalists on the scene and elsewhere, professionals and amateurs, affiliated and independent, advertisers, and sponsors engaged in the push and shove for access and control of the media event stage, narrative, symbols, public attention, and interpretation. The backstage production of media events has been much understudied, and this book makes a valuable contribution while again shifting attention toward the daily flow of events, toward history, and away from ceremony. In fact, the book was completed before the Games opened and there is not one chapter on what happened then; the ceremonial has no place in the book, only the context of its preparation.

In concluding these studies Dayan (2008) makes a series of points about the changing context and nature of media events. First, the semantic context, the mood of the world is more conflictive in recent years than it was in those hopeful years when the first media events work was done; now, Dayan proposes, events produce division and conflict as much as they bring people together. The progression of the Olympic torch around the world before the Chinese games opened, for example, became the locus of repeated protests, conflict, and attempts at censorship. The syntactics of media events have changed too, as the elements of their form have been used throughout the media to make ever more instances of ordinary news or entertainment, a bit more eventful, and thus reducing the unique attractions of more traditional events like the Olympics. The pragmatics, then, have changed too as the call of a ceremonial media event to a 'we' has become profligate, with daily, hourly claims on loyalty we no longer have to give to the media. The call or the claim that we have a collective identity has become banal and lost its power. Dayan sees, then, as others do, a disenchanted world in which the magic of the ceremonial media event no longer has much power.

These articles have been widely interpreted as a major revision of the concept of a media event, or even an abandoning of it, claiming that media events no longer work as they once did.

There is an alternative view, though. Rothenbuhler (2010b) argues that ceremonial media events, disruptive events, integrative events, disaster marathons, conflict events, denigration rituals, and all of the other forms that have been proposed are usefully conceived as varying instances of ritual communication.

As instances of ritual communication each of these phenomena is communication according to form that enables participation in serious life, even when implicitly so. Ceremonial media events are explicit in following ritualized forms and in their claim to be doing, as well as portraying, serious things, such as in a presidential inauguration. News coverage of crises, disasters, terror, and war may not be intentionally or explicitly ritualized, but it often is nevertheless (Coman, 2005). The ritualized elements of this news coverage work in the same ways as such familiar and intentionally planned ritual communication forms as the wedding ceremony: They are both self-referencing, self-steering, reality constituting symbolic systems; they both tend to create the worlds they portray (Rothenbuhler, 2010a). The disaster marathon may have attracted, and deserved, critical attention from Leibes and other scholars for violating the rationalist principles of journalism and producing more fear, conflict, and division. Its production of those consequences, though, depends precisely on those formal elements, as shown when the coverage of terrorism becomes routinized (Liebes and Kampf, 2007). It is not only history, but the form of the 'ceremonial' that changes and produces changed outcomes.

Conclusion

In sum, media events represent an important social form of dispersed ceremony. It is a form that raises important questions. On the one hand are questions about the power of communication and the necessity of the face-to-face context. On the other hand are the host of questions arising from the incongruity of serious, quasi-religious social functions being served by media normally devoted to entertainment, news, and profit. It is a form that can be abused or inappropriately imitated by politicians, government, the media, and other institutional interests.

The study of media events has also generated productive intellectual debates and the concept has been adapted to a broader range of examples, including conflict and social change, as well as the originally studied integrative, ceremonial events, and has been reconsidered and revised to fit changing media systems and historical circumstances.

Media Imperialism

Abstract

Media imperialism was a key critical interpretive paradigm in international communication in the 1960s. It prompted a considerable body of empirical research and was used in support of key policy concerns such as the New World Information and Communication Order. Yet as the transnational media environment develops, the paradigm is increasingly criticized from a number of vantage points: from historical process and effects, from production and flow, from audiences and effects, from genre, from media policy and regulation. As media industries around the world come of age and as globalization processes spread, including massive movements of people as well as of images, 'media imperialism' is of diminishing use in understanding contemporary cultural processes, although its underlying concern about the hegemony of Western, primarily US, cultural domination remains a live concern.

'Media imperialism' has been one of the most influential models in international communication. It has given rise to a significant body of empirical research, considerable theoretical debate, as well as support for international policy interventions about global communications imbalance. However it is increasingly subject to critique, particularly as a reflection of a particular moment of international media history that is now passing.

The Broader Paradigm of Cultural Imperialism

Media imperialism needs to be seen as a subset of the earlier and broader paradigm of 'cultural imperialism' that is most closely associated with Herbert Schiller (1969, 1976). This critical Marxisant paradigm itself developed out of broader critiques of the triumphalist paradigm of 'modernization' propounded in the late1950s and the 1960s predominantly by US theorists. This 'dominant' model proposed a single global process of modernization through a unilinear diffusion of Western technologies, social institutions, modes of living, and value systems to the eponymous 'Third World' (Sreberny-Mohammadi, 1996). Critical views, especially those advanced by dependency theorists such as Gunder-Frank, saw the process instead as the spread of inegalitarian capitalism from a few core advanced industrial countries to the periphery, the South. In this process, the West was supplied with raw materials and cheap labor as well as with markets for their manufactured goods. The spread of Western influence was seen as establishing an ideological bulwark against the much-feared spread of communism.

Cultural imperialism, Schiller argued, 'best describes the sum of the processes by which a society is brought into the modern world system and how its dominating stratum is attracted, pressured, forced, and sometimes bribed into shaping social institutions to correspond to, or even promote, the values and structures of the dominating center of the sytem' (1976: p. 9). For Schiller, the carriers of Western cultural influence included communication technologies themselves, which were not value-neutral instruments but imbued with capitalist values; language (evident as English takes over as the global linguistic currency from the varieties of colonial linguistic heritage); business practices; the genres as well as content of soap opera, blockbuster film, popular music, etc. Schiller's view was US-centric, and he saw media as central elements in the global expansion of capitalism centered on the US, fueled by advertising and consumerism. In the context of the Cold War, US policy makers' promotion of the 'free flow of information' – with no trade or legal barriers to the production or movement of mediated cultural products – undoubtedly helped the spread of US hegemony in ways that were consonant with, if not totally driven by, US foreign policy.

Media Imperialism

Media imperialism, a more focused subset of this model, was defined as 'the process whereby the ownership, structure, distribution or content of the media in any one country are singly or together subject to substantial external pressures from the media interests of any other country or countries without proportionate reciprocation of influence by the country so affected' (Boyd-Barrett, 1977: p. 117). It differentiated between the shape of the communications vehicle, a set of industrial arrangements, a body of values about best practice, and media content, although it is the latter claim that received most research attention.

It highlighted both the issues around 'cultural invasion' as well as a more general imbalance of power resources. In essence, the model argued that the world patterns of communication flow, both in density and direction, mirrored the system of domination in the international economic and political order, the control by the West over the rest.

Empirical Research

Part of the strength of the paradigm of media/cultural imperialism was its compelling clarity, which gripped many a critical academic imagination, and which suggested many fertile avenues of empirical research. It precipitated numerous studies that sought to examine the unidirectional flow of mediated

product from the West to the South. The 'one-way street' of television traffic was mapped by Nordenstreng and Varis (1974); film production and distribution was studied by Guback and Varis (1982); international news flow by the IAMCR/UNESCO study (Sreberny-Mohammadi et al., 1985). Scholars investigated the reach and dominant role of Western news agencies (Boyd-Barrett, 1980), supplemented latterly by study of the televisual news agencies (Paterson, 1998). Others showed that Third World media organizations were modeled on those of the earlier mother empires (Katz and Wedell, 1977). More recent studies detail the on-going transnational processes of conglomeratization and the increasing vertical and horizontal linkages of media corporations (Herman and McChesney, 1997).

Cultural imperialism and media imperialism were among the first models to take the global dynamics of media production and diffusion seriously. These paradigms posed important questions about cultural homogenization, about the diffusion of values such as consumerism and individualism, and about the possible impacts of Western media product on indigenous cultures in the South (Hamelink, 1983).

Political/Policy Struggles

These models also provided the conceptual and empirical framework for the NWICO (New World Information and Communication Order) debates which preoccupied UNESCO and the nonaligned movement through the 1970s until the USA, the UK, and Singapore walked out of UNESCO in 1984–5 (see Vincent and Galtung, 1992). The MacBride Commission gathered input from over 100 international experts, and in its final report, *Many Voices, One World* (UNESCO, 1980) challenged as inadequate the prevailing idea of 'free flow of information' since it functioned to privilege Western hegemony and cultural diffusion and to turn the South into mere consumers of Western news values, entertainment, and advertising images. Instead the report suggested the important qualification of a 'free and balanced' flow, which was adopted as UNESCO policy, although it defaulted from precise suggestions as to how, for example, international news coverage could be appropriately 'balanced.'

It is significant that UNESCO funded many of the early landmarks in critical international communication research yet from the mid-1980s, its focus and rhetoric has shifted toward a more neo-liberal position and a greater concern with issues around freedom and democratization than around balance/flow.

The debates about global media inequality and concern about the logics of conglomeratization and the threats to local cultures continue even in 2001 at the forums of the MacBride Round Tables; the demand for a Peoples Communication Charter and in the activities of the Cultural Environment Movement (see Voices 21, 1999). However, while the debates in the 1970s involved Third World policy makers, the critical voices are now mainly Western academics, while Southern politicians have become more involved in nitty-gritty decisions around deregulation, digitalization, and media convergence.

Critiques of Media Imperialism

Arguments From and About Historical Process and Effects

'Media imperialism' was a problematic argument both theoretically and empirically from the beginning, and by year 2001 it appears increasingly ossified. An argument that might have had some validity for some countries at a certain period of time became the dominant critical paradigm, operating as a form of political correctness by which critics were seen as apologists for the USA and its demand for a 'free flow international regime for trade in cultural products' (Sinclair et al., 1995: p. 6). By the 1980s when the global television and other media industries really changed shape, the 'critical' paradigm had become the 'orthodoxy' (Sinclair et al., 1995: p. 5).

Historically it is doubtless the case in most, especially technologically based, endeavors that the prime mover sets the model: in cars, in high-rise architecture, in media. Broadcasting did not develop with world domination in mind, even if some of its spread has been consonant with Western foreign policy interests. However, the model of state-controlled broadcasting which was adopted in much of the South hardly supported the 'free flow of information' of Western interests. It is also the case that subsequent media players 'catch up,' begin to produce their own content, and rework genres to fit their cultural habits. Already in the 1970s, Tunstall (1977) was arguing that Latin America's high level of television imports in the 1960s was a transitional phase while nationally based television systems were being established.

Empirically, it is mainly from the 1990s with the expansion of global satellite systems and development of infrastructure that much of the population of the rural South has actually been introduced to television. Thus, oddly enough, media could not have had the strong effects imputed by the model (nor by the modernization theorists like Lerner, 1958) because the televisual media actually didn't reach most people in the South until the satellite expansion of the late 1980s.

The crude adoption of 'media imperialism' arguments promoted a truncated historical analysis and tended to disregard earlier historical processes. It is probably the case that the cultural legacies of imperialism – the spread of Christianity, training in and use of European languages, establishment of systems of schooling and higher education, spread of administrative cultures – have had more enduring and far-reaching effect as carriers of Eurocentric modernization to the South than have the subsequent arrival of electronic media (Sreberny-Mohammadi, 1997; Bitterlli, 1989).

Additionally, many other industries, connected to but not reducible to the media industries, produce and market symbolic goods (fashion, foodstuffs, architecture and interior design, consumer durables) while the global tourism and travel industries literally transport millions of people a year. A focus on only one element of the contemporary production of culture cannot be read for the whole. Capitalism is also not organized and instituted through media, albeit that media content diffuses images of the goods, lifestyles, attitudes that are increasingly commodified and available for consumption in the capitalist market. In that sense, the media can support

processes of economic transformation and the profound shift from culture as 'practice' to culture as 'commodity,' and here reconnect to the bigger issues around modernization and development that tend to become submerged in the focus on media structures alone.

Arguments About Production and Flow

'Media imperialism' was a model developed at a time of comparative media scarcity and newly established broadcasting structures in the South. By the year 2001 there are many significant cultural industries in the South: Globo in Brazil, and Televisa in Mexico produce telenovelas; a huge multimedia complex near Cairo supports the production of Islamic soap operas, which Turkey also produces. And if the focus shifts away from television alone to include other cultural products, the diversity increases: Bollywood, the familiar label for the Indian film industry, is the Eastern challenge to Hollywood in the sheer number of film titles produced yearly, with the Asian diaspora constituting a sizeable audience. The Iranian and Chinese film industries are gaining global recognition and audiences. The marketing of 'world music' has helped the diffusion of Algerian, Senegalese, Cuban, and Brazilian contemporary music. The Indian Zee-TV is a powerful independent newscaster while Qatar's Al-Jazeera is revolutionizing factual programming in the Arab World.

Thus the model's metaphors of the 'one-way flow' down the 'one-way street' from the West to the rest (Nordenstreng and Varis, 1974) are challenged by more diverse production, and more complex images of the 'patchwork quilt' (Tracey, 1988). Southern media exports into the West have been dubbed 'reverse imperialism' while many of the new media mogul empires are not based in the West and Asian corporations and entrepreneurs (SONY, Masushita) have bought up segments of Western media.

Arguments About Audiences and Effects

'Media imperialism' also implied direct unmediated effects of television programming on audiences, turning them into Americanized consumers. It tended to ignore the particularities of local culture and their meaning systems as well as other processes of modernization (shifts in material production, migration and tourism, political institutionalization and democratization) that often operate alongside media development.

New approaches to the 'active audience' within media studies have forced a rethinking of international effects also. As with domestic viewing practices, analyses of the negotiation of meanings around US-produced programs such as Dallas by 'foreign' audiences show different audience viewing strategies including the imposition of local interpretive frames on 'foreign' media product (Liebes and Katz, 1990). There is also strong evidence that audiences prefer locally made mediated culture where and when that becomes available (Sepstrup and Goonasekura, 1994). The original logic of argument also depended on a rather ossified notion of 'national' culture, whereas even US product changes, so that the *Cosby Show* has become a popular, if rather inaccurate, symbol of changing race relations in the USA.

All this means that a single global product doesn't always work across cultural divides. While a film such as *Titanic* may have global reach, falling into that magical, much-desired and heavily marketed category of the 'global popular,' most media production is now tailored for local, that is, linguistically bounded, sometimes still nationally-bounded, cultural markets. The mantra is to 'think global, produce local.'

Regional linguistic-cultural markets are growing in economic significance as the 'cultural discount' (Hoskins and McFadyen, 1991) of local cultural preference kicks in. While this can produce regional exchanges of news and television programming, it can also produce localized versions of the old paradigm, as in the concern about India's cultural dominance over the subcontinent.

Arguments About Genres

Discussion about the nature and definition of media genres in relation to the South has perhaps not been fully engaged. The advent of an externally originated cultural form into a society has often caused controversy in, for example, fear about the impact of free verse on traditions of formal poetry or about the impact of the novel on non-Western writing cultures. Yet now Latin American magic realism and postcolonial family sagas crossing generations and national boundaries have transformed the very form of the novel. A debate once raged about whether Latin American telenovelas were a new form of television series, inflected with socially developmental themes, or whether they were simply soap operas with commercial promotional messages. Anthropologists have analyzed the rise of the Islamic soap opera (Abu-Lughod, 1993) and it seems clear that Southern media texts are not 'simply' copies of Western texts, but neither are they utterly novel genres either. Textual give and take, multiple sources of inspiration and derivation in media content, needs to be taken seriously, and attention paid to how forms evolve over time, both within developed television industries like the USA and the UK as well as within 'younger' media systems. For example, Zee-TV is not the same as MTV, although it may also show music videos.

Arguments About Media Policy and Regulation

As the global media environment changes with growing convergence between broadcasting and telecommunications, growing digitalization and the spread of the Internet, so there has also been a move from notions of imperialism to ideas of cultural hegemony. Such constructs are less overtly spatial and usefully deconstruct a singular and unproblematic 'West.' There have been fierce intra-Western disputes, most obviously the French disagreements about the deregulated flow of US film within GATT talks, or the differences and competition between US and UK modes of news construction. Parts of South East Asia may now be more concerned about the dominance of Indian cultural product than US; and national law in one Western country encounters a different set of rules in another, as in the US-French dispute about the sale of Nazi ephemera through the Yahoo gateway on the Net.

Arguments About the State and Democratization

The concern of much of the debate with transnational media domination by the West and the dominance of the market often precluded serious analysis of national processes, particularly the complex class formations in the South and the role of states. Thus, for example in Latin America, repressive military juntas have used media as key institutions of authoritarian government (Waisbord, 2000) while in rapidly modernizing South East Asian economies the ruling elites have aligned with global corporate interests, often against the needs of their own population. As popular movements for democratization and equality have grown inside such states, this has prompted greater analytic focus on the relations between transnational processes and national politics and media control, and how states and markets interact within different political and economic formations.

It is amongst the autocratic, sometimes religious, regimes of the Middle East and South East Asia that the argument about 'media imperialism' is still heard. The 'protection of indigenous culture' can be used as a weapon to prevent internal change and demands for democratization, and the 'outside' can be constructed solely as a predator involved in acts of rape against the feminized, vulnerable nation. Yet, in numerous Southern countries – Indonesia, Nigeria, Iran, Brazil – secular intellectuals, ethnic groups, and women are struggling for greater political openness and basic human rights as well as a media environment which facilitates the construction of an inclusive national public sphere. Sometimes the transnational space can act as one of solidarity and support for such struggles.

The Rise of 'Globalization'

Many of the early debates around cultural imperialism and media imperialism actually prefigure key strands of argument that were taken up by the rhetoric of globalization in the 1990s: the recognition of the collapse of space and time through communications technologies; the commodification of social life; the significance of cultural flows. But within the model of globalization is also a sense of collapse of the older, single-centered hegemon into a more disorganised post-Fordist set of global production processes (Lash and Urry, 1994); a more decentered and unstable political and cultural environment; and a variety of resistances to Western modernity with the rise of primordial religious and ethnic loyalities. The interpenetration of the global and local actually produces multiple formations of modernity.

'Cultural imperialism' tended to see cultures as singular, somewhat ossified, nationally bounded entities: 'American' television impacting on 'Iran,' for example. There is increased awareness of the loosening of the hyphen in the nation-state and thus the 'national culture' is better seen as a site of contest. These are not just issues for countries in the South, but for most countries around the world. In the UK, this is enacted politically with the devolution of Scotland and Wales, and in debates around immigration policy; and culturally by debates about the religious content of the millenial exhibition in the Dome, and about the representation of ethnic minorities in the media. National identity may be practiced daily through a variety of symbolic forms and organizational routines, but its actual content may be more fluid and disputed than ever.

Globalization highlights the manner in which pressures to modernize are being met with particular local orientations and practices. It can still be argued that Western values lie hidden behind a seemingly neutral 'universal' and abstract set of processes, but the precise way these are encountered, understood, and dealt with varies from country to country, even within the same region. Latin America presents considerable national variation as does the Arab world; hence, even an increased awareness of regionalism is insufficient. Among media academics, more particularism, more case studies, more nuance is required.

The real collapse of the three worlds of development has left a conceptual lacuna. It is hard to propose such totalizing models any longer. Rather, we need regional frames that take cultural specificities, local structures, political values, seriously. Globalization has exacerbated economic disparities among – but also within – countries and has not ended political repression. Contemporary 'flows' include massive movements of capital and of people, so others are no longer 'there' but 'here' and building transnational communities through various kinds of diasporic media.

Work on the media has also tended to be focused on a single medium, initially mainly television, now heavily focused on the Net; yet rather bizarre situations exist whereby entire newspapers are banned, for example in Tunisia, Egypt, and Iran, while Internet-based information circulates with impunity. Looking at only one element of a complex media environment can also lead to wrong conclusions.

A recent attempt to rework the 'media imperialism' model suggested the need to 'encompass neo-colonialisms of inter-ethnic, inter-cultural, inter-gender, inter-generational and inter-class relations' (Boyd-Barrett, 1998: p. 167) but instead helps us to recognize that in the end the model is simply about power imbalances, which do not require the 'imperial' stamp to be of importance to examine. Indeed the 'imperialism' obscures the differentiated processes of economic inequality and complex power dynamics. Access to cultural expression often involves complex internal struggles for power as well as pushes from the outside. As Tomlinson (1991) has argued, cultural imperialism always consisted of many different discourses; the on-going attempt to rewrap them into one through the trope of 'media imperialism' is an increasingly forlorn task. The world has changed and so must our language and our theoretical frames.

Conclusion

Perhaps the enduring cultural legacy of the USA lies in the development of a commercial model of television as a medium: using entertainment content to attract audiences who could be sold to advertisers (Sinclair et al., 1995). While this is still not a universal model and many states still try to control broadcasting, commercial pressures and availability of multiple forms of media distribution/reception such as satellite and cable mean the globalization of capitalism and the

manufacture of mediated culture are in the ascendant. In that sense, the focus on US-centric media diffusion obscures a far wider concern around the generic mass production of culture that is now flourishing globally.

Editor's Note

The domination of mass media and the larger culture by, at most, a few Western institutions continues to be a prominent research theme in media studies and mass communications research. Media Talk Shows

Andrew Tolson, University of Leicester, Leicester, UK

© 2015 Elsevier Ltd. All rights reserved.
This article is a revision of the previous edition article by A.G.D. Leurdijk, volume 23, pp. 15437–15440, © 2001, Elsevier Ltd.

Abstract

There are different definitions of media talk show ranging from news and current affairs, to celebrity interviews and audience participation programs. A comprehensive account might also include talk radio formats, such as call-ins, from which the pioneering American TV talk show, *Donhaue*, was developed. This article distinguishes between five variants, or subgenres, of this type of TV talk shows: the audience discussion format, the focus on social identity, therapeutic talk shows, confrontation programs, and belligerent interrogation. Through these various formats the role of the 'ordinary person' has changed, from 'sociable' forms of audience participation to individuals becoming the recipients of authoritarian moral judgments.

Definition

The fact that most forms of electronic media, including some uses of the Internet, involving people talking, might lead to the conclusion that there is a wide range of media 'talk shows.' This is indeed how some discussions proceed, using the term to refer to genres as diverse as news and current affairs (particularly breakfast news programs and late night debates) and celebrity interviews (or 'chat' shows) as well as audience participation programs. Furthermore, there are of course media enterprises explicitly dedicated to 'talk,' such as talk radio stations structured around phone-ins. More broadly still in contemporary culture, 'talk' is promoted as having a certain moral value, as in the slogan "It's good to talk" adopted by the UK company British Telecom (and used in the title of an important book on this topic – see Cameron, 2000). This validation of talk is not only used as a means to sell mobile phones, but it also catered for, in various ways, by conventional broadcast media.

However a moment's reflection suggests that there are some distinctions to be made. Programs differ generically in terms of their location, their participants, and crucially by the role of the audience. A breakfast news program is studio based, with 'talk' taking the form of announcements, reports, and live 'two-way' interviews between anchors and fellow journalists. There is no live audience here. On late night debates and celebrity interview shows the participants are public figures, and though there is a live audience, opportunities for its participation are restricted and in most chat shows it is invisible. The formats for (usually daytime) audience participation programs do differ, but as the phrase suggests the role of the audience is less circumscribed, the participants are ordinary people and the setting is more theatrical, with the stage itself coming into focus, as 'backstage' areas are included. So even if the term 'talk show' has been used to cover current affairs debates (such as the long running BBC program *Question Time*) and celebrity interviews (such as NBC's *David Letterman Show*) as well as the daytime talk shows, it is nevertheless important to recognize the differences, and that increasingly, that the term is used exclusively to refer to the third of these formats.

(Pre)history

The broader context remains important however particularly for understanding the history of media talk shows. Here, there are two levels of analysis. Firstly, at the empirical level, it is instructive to trace the participation of 'ordinary' people in broadcasting. In both the USA and the UK this started with experimental radio programming in the 1930s. For example, Wayne Munson (1993) discusses the emergence of 'human interest' or 'vox pop' programs, as well as game shows, on American radio in the 1930s, as precursors to what was the first 'comedy audience participation' TV show, *Art Linkletter's House Party* (1952). In the UK, such audience participation was less extensive, but by the mid-1930s 'ordinary' (or working-class) people began to appear in radio documentaries and in what were known as 'character' programs. The vox pop approach was used in the BBC radio program *In Town Tonight* which featured its presenter, Michael Standing, 'standing on the corner' interviewing passers-by, defined, in the terminology of that era as 'the-man-in-the-street.'

On 24 March 1939 *The Radio Times* included a special supplement featuring Standing on its cover and an article entitled 'The Man in the Street is a veteran broadcaster.' This article provides a retrospective summary of the aforementioned documentaries, plus a radio series called *Harry Hopeful* which "brought all sorts and conditions of 'ordinary' men and women together in a happy party to entertain you at a common microphone." Clearly then the 'party' idea was not entirely absent from the BBC (even though contributions to *Harry Hopeful* were scripted) but the importance of this program is that it introduces a second level of historical analysis. As discussed by Paddy Scannell (1996) – see also Scannell and Cardiff (1991) – *Harry Hopeful* introduced to Britain a key principle of media talk, namely 'sociability' in which ordinary, conversational talk, for its own sake, is presented as entertainment. This relates critically to Scannell's theorization of 'broadcast talk,' that it is designed to appeal to overhearing audiences. Media talk, therefore, has a performative, and not just a communicative function, and this is a key point for understanding how talk shows have developed in the age of television.

TV Talk Shows

The evolution of the contemporary TV talk show can be seen as a combination of two developments, both discussed by Munson. The first development was the transition of 'audience participation' (or the use of 'ordinary' people as performers) from radio to TV. There was some overlap here between developments in the USA and the UK, largely because British commercial TV in the 1950s adopted many American formats. If *Art Linkletter's House Party* was the pioneer, this soon extended to a variety of game shows, quiz programs, and proto-reality TV (programs such as *Candid Camera*). However unique to America was the *Tonight* show which introduced an interesting variant of comedy talk involving its presenter Johnny Carson mingling with the studio audience. The second development was talk radio's use of phone-in programming which became popular in the USA in the 1960s. It was in 1967 that Phil Donahue introduced a phone-in program on WLWD-TV in Dayton Ohio, which then evolved into the TV talk show *Donahue*, by all accounts the pioneer of a new TV genre. By 1980 this show was a national phenomenon, syndicated to 215 TV stations, with a particular appeal to women, and a subsequent life span that lasted until 1996.

However, even within this relatively specific definition of what constitutes a 'talk show,' it is possible to identify five variations or subgenres. These range across a spectrum and have a 20-year history in which some of the longer running programs, such as *The Oprah Winfrey Show*, exhibit cross-over features. However, it is broadly possible to differentiate TV talk shows according to types of topic, the arrangement of studio settings, and the preferred forms of talk. The starting point for this survey is what has been termed the 'audience discussion format' (Haarman, 2001), based on the American model of the 'town hall' format, still used in some televised presidential election debates. Here social issues (juvenile crime, job discrimination, and police conduct) are debated by a collective 'public' consisting of ordinary people, experts, and sometimes politicians.

Crucially, in audience discussion programs there is no stage – participants are seated in the round, with no particularly privileged place for the experts, and everyone has access to a mobile microphone controlled by the host. For some commentators (Carpignano et al., 1990: p. 49), this represents a 'crisis of theatricality' creating a new kind of 'public sphere' which transforms the traditional separation between an audience and its (on stage) representatives. What it certainly achieves is a forum in which different forms of public discourse are in circulation and sometimes in conflict. In Sonia Livingstone and Peter Lunt's (1994) account, there are two major 'epistemologies' in play, where participants demonstrate different kinds of knowledge of the issues under discussion and where, because of the setting, no particular type of knowledge is inherently superior.

In this public sphere experts and politicians speak from institutional perspectives, on professional 'footings' (Goffman, 1981), whereas ordinary people speak the language of 'commonsense.' There are two particular manifestations of this difference. The first is 'entitlement': whereas the expert has a preestablished institutional entitlement to speak (and is introduced as such), the ordinary person has to establish his/her entitlement in the act of speaking (e.g., by referring to their occupation or marital status). This then leads to a second discursive feature, the personal narrative; the knowledge of the ordinary person is grounded in experience and one of the most effective ways of communicating this is through oral narrative or 'anecdotes' (Tolson, 2006). In audience discussion shows anecdotes have a significant rhetorical effect; when told well they are dramatic extended turns at speaking which lay claim to moral truths (cf Labov, 1972).

It is a short step from this use of personal narrative to a second variant of the talk show. This is where issues are selected for discussion primarily to evoke personal perspectives and/or the display of social identities. Issues such as race and gender discrimination, sexual preferences, unconventional domestic arrangements, and so on, cross the boundaries between public and private limits. Their discussion can facilitate 'coming out' in expressions of cultural diversity and 'identity politics.' In Jane Shattuc's (1997) account of the 'Oprahification of America' this involves a kind of therapeutic discourse which is not so much the individualized psychoanalytic 'talking cure' (despite the title of her book) as the puritan-American tradition of public testimonial, or 'testifying.' This seems to have much in common with what Donal Carbaugh (1988) describes in a study of *Donahue* as 'talking American'; that is the performance of 'self' in terms of 'being honest,' self-aware, and where 'good communication' entails the 'sharing' of experiences.

A third variant of the TV talk show is where its rationale is more explicitly therapeutic. Here the focus is not on issues or identities but on the personal problems of dysfunctional, or at least unhappy, individuals. The purpose of the show is then to encourage such individuals to acknowledge and confront their problems, and to commit to change. Again Jane Shattuc is clear that this is not so much a Freudian practice (it cannot be such on a TV show) as a form of 'rational emotive therapy' which is allied to consumer-oriented lifestyle choices. A classic example of this would be a problem such as 'comfort-eating' (or similar forms of addiction) where the prescription might be a more carefully controlled diet. As regards the talk show format, this shift to the therapeutic is signaled by three generic features. Firstly, program titles are typically expressed in the first person, from the point of view of a complainant. Secondly, the role of the professional expert has shifted to that of 'after-care' specialist, where that person might be part of a backstage 'support team.' Thirdly, on stage, the defining moment of such shows occurs when the dysfunctional individual, having acknowledged his/her problem, makes a public commitment to change. Often this involves the performance of a speech act (Austin, 1962) such as a public vow or promise, which is greeted by a round of audience applause (Tolson, 2006).

Mention of the 'on stage'/'backstage' arrangements in some therapeutic talk shows heralds a fourth key development. Gradually, and despite the interesting point about the transformation of 'theatricality' made by Carpignano et al., in some TV talk shows, stage-like seating arrangements, which separate performers from the audience, have been reintroduced. In therapeutic talk shows the audience remains seated in the round and microphones are passed to members to make comments. However guests, and sometimes presenters, occupy a separate, central, studio floor. In this subgenre, presenters interview guests, to formulate their problems for subsequent audience comment. Audiences too speak the language of

therapy and express their commitment to the values of 'good communication.'

Further development occurs when theatricality becomes a show's defining feature. As Shattuc describes it, this shift occurred in the USA in the mid-1990s when TV producers discovered a youth audience for TV talk shows. Here, the fact that the problems in therapeutic talk shows were often expressed in the form of complaints (made by one partner in a relationship to another) was now taken to a further level of staged confrontations between accusers and accused. Interviewing was now a residual feature, simply a matter of introducing complaints for protagonists to pursue, to argue their differences on stage and with members of the audience. Talk shows now staged conflicts between identities that were pre-established and fixed, rather than issues to be discussed or personal problems to be resolved.

On *The Jerry Springer Show* (widely distributed in Europe as well as the USA) such confrontations escalate into physical fights, with bouncers employed to restrain participants. The verbal exchanges too seemingly break boundaries of acceptable broadcast talk, with utterances bleeped out, creating the ironic situation of a 'talk show' where some of the 'talk' cannot be heard. Two sorts of argument have been made about this. Firstly, Lunt and Stenner (2005) have suggested that *Jerry Springer* too can be understood as a kind of therapeutic situation – where the exteriorizing of emotion ('acting out') provides a release for the inarticulate. The second argument, made in Shattuc's (1997) discussion of *Riki Lake* suggests that such talk shows are a form of melodrama – a modern version of a nineteenth century popular theatrical form (vaudeville or pantomime), with excessive displays of behavioral 'flooding out' served up for audiences to react with populist moral assessments (see also Myers, 2001).

In the final variant of a TV talk show, such assessments are expressed, not by the audience, but by the host. Whereas Jerry Springer supervises proceedings from a position of ironic distance (and stands with the studio audience), Jeremy Kyle advances from the audience to the edge of the stage, to deliver moralistic harangues to his hapless guests. The 'harangue' is a belligerent face-threatening act which has the force of an absolute moral truth, and is often supported on *The Jeremy Kyle Show* by 'evidence' in the form of DNA and lie detector tests. It is the climax to an extended sequence of aggressive interrogation and is always greeted by applause and cheering from an audience which otherwise does not contribute (see Tolson, 2013). The fact that many of the 'guests' that appear on *Jeremy Kyle* are (like *The Jerry Springer Show*) recognizably from the lower working class (where DNA tests for example are used to resolve paternity issues) is a matter for discussion below; but what it illustrates for the talk show genre is a situation where 'audience participation' has been reduced to responding to a performance in which the host/presenter is the star and the collective discussion of issues or problems has been entirely displaced by authoritarian moral judgments.

Evaluations and Critical Perspectives

Together with so-called 'reality television' (and the phenomena are closely related) TV talk shows have, in the past 20 years, received extensive commentary, both journalistic and academic. Some of the journalism has focused on the 'scandalous' aspects of some talk shows (revelations about fake guests and the alleged 'effects' of talk shows on pathological social behavior – see Gamson, 1998). In the opinion of some academics (Abt and Seesholtz, 1994) this can amount to a 'crisis in the social construction of reality.' More generally, much academic commentary has not only focused on the 'blurring of boundaries' in talk shows, particularly between public and private, but also in the challenge to social norms provided by the relentless 'display of deviance.' At times, refracted through the lens of journalistic sensation, this has seemed like a kind of 'moral panic' (Thompson, 1998). However it has also been interpreted more positively as a 'postmodern' challenge to conservative social categories (Munson, 1993).

We have already encountered the idea that some talk shows might constitute an alternative or 'oppositional' public sphere. Here the argument is that previously suppressed voices are given a public hearing that challenges "the dominant ideology conveyed by television" (Carpignano et al., 1990: p. 50). In this view an alternative politics 'emanating from social, personal, and environmental concerns' (what Anthony Giddens (1991) called 'life politics') becomes conceivable. Perhaps not surprisingly, this view has been particularly popular with some feminist academics who have argued for instance that *The Oprah Winfrey Show* 'scandalizes' the dominant culture in its tolerance, and even the encouragement of 'excessive' forms of communication (Masciarotte, 1991). There has been an extensive subsequent debate between 'positive/radical' and critical feminist perspectives (summarized by Tolson, 2001) with the latter perspective arguing that the language of therapy is unable to form political perspectives that effectively challenge social oppression. For Shattuc (1997) talk shows are not feminist because they fail to deal critically with patriarchy. For Gamson (1998), who writes from a gay perspective, TV talk shows represent a 'tightrope of visibility,' where sexual nonconformity becomes public precisely in the context of its representation as 'deviance.' Whatever kind of public sphere this might be, it is fraught with contradictions.

A critical perspective on talk shows also has to recognize the contexts of its industrialized production. Here again, Jane Shattuc provides useful data. As a staple of the mainstream TV industry for 25 years their growth is clearly related to three key developments: firstly the proliferation of TV channels, secondly the introduction of continuous daytime schedules, and thirdly the significance of 'demographics' in contemporary marketing. As Shattuc makes clear, this is cheap daytime television popular with a predominantly female (conceived as 'housewife,' though more latterly also 'youth') demographic. It is used to advertise cosmetics, personal care, and domestic products. However, that context in itself does not explain the particular format of the talk show (for daytime soaps also appeal to this audience and are used to advertise similar products). To the industrial history there needs to be added a critical/generic perspective, and this is provided by John Dovey (2000).

In his book *Freakshow*, Dovey charts the development of what he calls 'first person media.' This includes camcorder and 'reality' television as well as TV talk shows (and had he been

writing 5 years later he might have included some uses of the Internet such as YouTube). Importantly, he relates these developments to 'neoliberalism,' the dominant political and cultural ideology built around the central figure of the individual consumer. Such TV programming supports neoliberalism not only by advertising consumer goods, but also in its focus on self development (the therapeutic agenda of many talk shows) and the cultivation of 'lifestyle.' This ideology is promoted not only in advertising on commercial television, but also in the talk show's focus on personal development and self-realization.

Since the 1980s there has been an international narrative to neo-liberalism, developing from the deregulation of banking and spread of financial services to increasing levels of individual consumer debt. The consequent crisis of 2008, and the shift in most Western economies toward an age of austerity, has provided a context in which the more belligerent talk shows have flourished. This is not to say that talk shows have simply reflected that context, still less that they have discussed it, but rather that their theatrical display of belligerence resonates with a neo-conservative perspective on social deviance. If credit-fuelled consumerism was partly to blame for the crisis, this was most visibly represented by an unsustainable lower working class (in the UK 'chav') consumer lifestyle; and if the dominant response was to be cuts on public spending, where better to start than from dysfunctional families living on welfare? This class fraction has become the *dramatis personae* of the melodramatic and moralistic forms of talk shows which, transmitted as they are by the more popular commercial TV stations, reproduce a populist social agenda (Tolson, 2013). Accordingly, it is instructive to reconsider what these forms of broadcasting are doing now compared to the introduction of 'ordinary people' in 1930s radio, which by coincidence, following the great depression, was also an age of 'austerity.' Whereas the ordinary person then was given a sociable voice to be celebrated; today it seems, in the authoritarian discourse of *Jeremy Kyle*, the opposite is true.

Abstract

A mediating variable is intermediate in the causal sequence relating an independent variable to a dependent variable, such that the independent variable causes the mediating variable that causes the dependent variable. Theoretical mediating variables are common in the social and behavioral sciences and several examples are given in this articles. The major approaches to investigating mediation with statistical methods and experimental designs are outlined. New methods to investigate the role of confounding variables and approaches to improve causal inference from mediation studies are described. A program of experimental, statistical, and qualitative research for the investigation of mediating variables is emphasized.

A mediating variable explains and identifies the causal process underlying the relationship between two other variables. A mediating variable (M) is intermediate in the causal sequence relating an independent variable (X) to a dependent variable (Y), such that the independent variable causes the mediating variable and that, in turn, causes the dependent variable. Mediating variables are known as intervening variables or intermediate variables because they come between the independent and the dependent variables. Important aspects of mediating variables are their close link with theory and the potential that the mediating variables identified in one context may operate in a wide variety of contexts. This article starts with examples of mediating variables, outlines tests for mediating variables, and describes limitations and extensions of mediating variable models.

The Mediating Variable Effect

When quantified, the mediating variable effect is known as the mediated or indirect effect. It is called the indirect effect because it represents an effect of X on Y that is transmitted indirectly through the mediating variable. If some, but not all, of the effect of X on Y is transmitted through M, the effect is partially mediated because a direct effect of X on Y exists even after adjustment for the mediator.

The mediating variable effect differs from other third-variable effects used to understand the relationship between two variables. For a moderator or interaction variable, the relation of X on Y differs for different values of the moderator variable. Unlike a mediating variable, a moderator does not transmit the effect of X on Y. A confounding variable, when included in the investigation of the association between X and Y, changes the association between X and Y. A confounder changes the association between X and Y because it is related to both X and Y but not because it is in a causal sequence relating X to Y. Although the conceptual distinction between a confounder and a mediator is clear, it can be difficult to differentiate between them with actual data. The underlying causal sequence X to M to Y is the important aspect of the mediating variable.

Examples of Mediating Variables

Because the mediating variable elaborates the relationship between two variables by explaining why or how an effect occurs, it is of considerable importance in many fields. One of the first applications of the mediating variable was in psychological theories for how a stimulus is translated into a response. For example, habit strength (Hull, 1943) or appetite (Tolman, 1938) may intervene between stimulus of a maze (X) and response time (Y) to complete the maze. Later, a distinction was made between hypothetical mediating constructs representing processes or entities not directly observed and intervening variables that were observed measures of these hypothetical constructs (MacCorquodale and Meehl, 1948). Duncan (1966) established the use of mediating variables in sociology when he applied path analysis techniques developed earlier by Wright (1934) to examine causal mediating relations among variables. One of the first sociological examples was that father's socioeconomic status causes the mediating variable, child's educational achievement, which causes child's socioeconomic status. The effect of father's socioeconomic status on child's socioeconomic status was not entirely mediated by child's educational achievement, so a direct effect between father's and child's socioeconomic status also was included in the model. Decomposition of effects into direct and indirect effects is a common focus of sociological research.

Another application of the mediating variable is in chronic disease research (Schatzkin et al., 1990). Prospective studies examining the effects of etiological factors or prevention strategies on chronic disease require lengthy follow-up measurements because of the low frequency of occurrence and the slow development of the disease. As a result, researchers attempt to identify mediating variables on the causal pathway relating risk factors to disease. The mediating variables are called intermediate or surrogate endpoints. Using colon cancer as an example, the proliferation of epithelial cells in the large bowel occurs before colon cancer and is related causally to colon cancer. A study targeting cell proliferation rather than colon cancer requires less time and fewer subjects. The use of these endpoints as a surrogate for the ultimate endpoint is an active area of research with unique substantive and statistical aspects. The focus of surrogate endpoint research is typically a single intermediate variable rather than the multiple mediators common in sociology and other areas of social science. It often is expected that the relation between the surrogate and ultimate outcome is close to perfect.

Mediating variables are critical in the development and application of treatment and prevention programs. Programs

 http://dx.doi.org/10.1016/B978-0-08-097086-8.44037-7

are designed to change mediating variables hypothesized to be related causally to the dependent variable. It is assumed that the program causes change in the mediating variable, which, in turn, causes change in the dependent variable. Programs to prevent coronary heart disease target mediating behaviors, such as diet and smoking, and biological factors, such as cholesterol level and blood pressure. Social influence-based drug prevention programs are designed to increase skills to resist drug offers and engender norms less tolerant of drug use. Treatment programs for substance abuse target mediators, such as communication skills and social support, to prevent a relapse to drug abuse. Tobacco treatment programs seek to reduce craving for nicotine to reduce remission. Cognitive behavioral approaches to depression treatment focus on cognitive reinterpretation of life events.

Theories of health behavior and empirical relationships from prior research guide the selection of mediating variables for treatment and prevention programs. The selection of mediators based on their relation to the outcome variable has been called the conceptual or etiological theory of an intervention. An intervention based on established theory regarding mediating variables may be more likely to change the outcome measure, and the results provide a test of the theoretical basis of the intervention. Competing theories of the onset of drug abuse, for example, may suggest alternative mediators that can be tested in an experimental design. Prevention and treatment programs will cost less and have greater benefits if effective and ineffective mediating processes are identified. Unlike prevention, which serves to prevent problem behavior from occurring, treatment programs target mediators to stop a problem behavior from reoccurring. As a result, mediating variables selected for treatment may be different from those selected for prevention for several reasons. The delivery of prevention is typically in large groups of people in contrast to treatment that is delivered individually or in small groups. The source of treatment may include therapist actions, actions conducted by the client alone, actions conducted by the client as part of a group, pharmaceutical treatments, or changes in environment.

Mediating variables in prevention and treatment serve a different purpose than other applications of mediating variable methodology. In prevention and treatment, mediating variables are selected before the study and are fundamental to the prevention program because of their causal relationship to the dependent variable. In most other applications, the purpose of the mediating variable is to identify the processes that generated an effect, after the effect has been found. The approach of finding an explanation of an observed relation between variables can be traced to the work of Hyman (1955) and Lazarsfeld (1955). The design of interventions to target mediating variables is more recent and combines theory for which mediators are related to the outcome with theory for actions that will change the mediators as part of the intervention. Before an intervention study is conducted, researchers select mediators that are malleable during the intervention period that also are related causally to the outcome variable. In some cases, a mediator with a weaker relation to the outcome variable may be selected because it is easier to change by actions of the intervention.

Tests of the Mediated Effect

The single mediator model with symbols to represent relationships between variables is shown in Figure 1. The parameter estimates and standard errors from the following three equations provide the information for tests of the mediated effect (MacKinnon and Dwyer, 1993):

$$Y = \tau X + \varepsilon_1 \quad [1]$$

$$M = \alpha X + \varepsilon_2 \quad [2]$$

$$Y = \tau' X + \beta M + \varepsilon_3 \quad [3]$$

where Y is the dependent variable; X is the independent variable; M is the mediating variable; τ codes the relationship between the independent variable and the dependent variable; τ' is the coefficient relating the independent variable to the dependent variable adjusted for the effects of the mediating variable; α is the coefficient relating the independent variable to the mediating variable; β is the coefficient relating the mediating variable to the dependent variable adjusted for the independent variable; and ε_1, ε_2, and ε_3 code unexplained variability. The intercepts are not included to simplify the presentation. Two estimators of the mediated effect, $\alpha\beta$ and $\tau - \tau'$, are algebraically equivalent in ordinary regression but not in other analyses, such as multilevel and logistic regression.

Three major types of tests of the mediated effect use the information in the above regression models: (1) causal step tests, (2) difference in coefficients tests, and (3) product of coefficients tests. Methods to assess mediation based on causal steps entail tests of the different logical relationships among the three variables involved that must be true for a variable to be a mediator. The following sequence of causal steps described in Baron and Kenny (1986) is the most widely used method to assess mediation: (1) The independent variable (X) must affect the dependent variable (Y), τ in eqn [1], (2) the independent variable (X) must affect the mediator (M), α in eqn [2], and (3) the mediator must affect the dependent variable (Y) when the independent variable (X) is controlled, β in eqn [3]. The conceptual links between each necessary causal relationship and the statistical tests are clear in the causal step method. The causal step method, however, has no direct estimate of the mediated effect and standard error needed to construct confidence limits. The first requirement, a significant relationship between the independent and dependent variables excludes models where mediation exists, but the relationship between

Figure 1 The mediating variable model.

the independent variable and the dependent variable is not significant. The first requirement is consistent with the origination of this approach in the explanatory model described by Hyman (1955) and Lazarsfeld (1955) with the goal of explaining an observed relation among variables.

The second method to test for mediation compares the relationship between the independent variable and the dependent variable before and after adjustment for the mediator. The method tests whether a third variable, here a mediator, significantly changes the relationship between two variables. The difference in the regression coefficients ($\tau - \tau'$) is an example of this approach. Formulas for the standard error of $\tau - \tau'$ can be applied to construct confidence limits for the mediated effect (Clogg et al., 1992). A drawback of the change in coefficient method is that it is conceptually more similar to a confounding variable than to a mediating variable.

The third method to test the significance of the mediated effect is based on the product of coefficients, which is more consistent with the causal sequence in mediation. The estimator of the mediated effect is $\alpha\beta$, the product of regression coefficients α and β. The most commonly used standard error is the first-order Taylor series solution for the product of two random variables derived by Sobel (1982) using the multivariate delta method, where σ_α and σ_β are the standard errors α and β, respectively:

$$\sigma^2_{\alpha\beta} = \alpha^2\sigma^2_\beta + \beta^2\sigma^2_\alpha \qquad [4]$$

The matrix formulas for the computation of this standard error are included in most covariance structure analysis software programs. Confidence limits for the mediated effect can be calculated using the standard error in eqn [4], and the result is then compared to a standard normal distribution to test for significance. The mediated effect divided by its standard error, $\alpha\beta/\sigma_{\alpha\beta}$, however, rarely follows a normal distribution. Methods based on the distribution of the product of two random variables provide more accurate confidence intervals and significance testing than assuming a normal distribution. Methods based on resampling, such as the percentile bootstrap, also provide more accurate tests because they do not require that the mediated effect has a normal distribution.

The product of coefficients methods provides an estimate of the mediated effect and the standard error of the mediated effect. In addition, the underlying model is a mediation model in which the mediated effect is the product of coefficients hypothesized to measure causal relationships. For an independent variable coding experimental assignment, the α estimate tests whether the manipulation successfully changed the mediating variable it was designed to change, and the β estimate tests whether the mediating variable is related to the dependent variable, as suggested by theory. There are several important assumptions of the product of coefficients method, including reliable and valid measures and the usual linear regression assumptions of independence of errors across equations. The interaction of X and M in eqn [2] could be added, which tests whether the relation of M and Y changes across levels of X. The test evaluates the extent to which the mediation process differs as a function of the value of the mediator (MacKinnon, 2008). The method also assumes that causal relations among variables are accurate, which is an active area of recent research, as described in the next section.

Causal Analysis of Mediating Variables

Methods based on the regression approach described thus far have been criticized based on causal analysis of the relationships among variables. For example, if X, M, and Y are measured simultaneously, other models (e.g., X is the mediator of the M to Y relationship or M and Y both cause X) would explain the data equally well, and it is not possible to distinguish these alternatives without more information (Spirtes et al., 1993). The case in which X represents random assignment to conditions improves causal interpretation of mediating variables (Holland, 1988; Robins and Greenland, 1992). Holland applied Rubin's (1974) causal model to a design in which students are randomized to one of two groups, either to a group receiving motivation to study or to a control group that did not receive motivation. The mediating process is that assignment to the motivation group affects the number of hours studied, which affects test performance. Under some assumptions, the typical regression coefficient for the group effect on test score, τ, and the group effect on number of hours studied, α, are valid estimators of the causal effect, primarily because of the randomization of units to treatment. The relationship between the mediating variable of the number of hours studied and test score is more problematic (e.g., Y may cause M) and the regression coefficient β is not an accurate estimator of the causal effect because this relationship is correlational, not the result of random assignment. The estimator τ' is not an accurate causal estimator of the direct effect. The missing information for the causal effects is whether the relationship between the number of hours studied and test score would have been different for subjects in the treatment group if they had instead participated in the control group. The problem with causal estimation of mediation effects described by Holland has been more formally described as an assumption of sequential ignorability. Sequential ignorability is the assumption that omitted variables do not bias the X to M relation and omitted variables do not bias the X to Y relation (Imai et al., 2010; Lynch et al., 2008; ten Have et al., 2007). With random assignment, omitted variable bias is balanced for the relation of X to M so that α is an estimator of a causal effect. The influence of omitted variables on the regression coefficient β cannot be interpreted as a causal effect even when X is randomized, because the value of M is not randomized to individuals but rather is self-selected by participants. The estimator, τ', is also not an accurate estimator of the causal effect of X on Y, controlling for M for the same reason. The limitations of interpreting the β coefficient as a causal effect have been described in several different substantive areas but with somewhat different nomenclature (Robins and Greenland, 1992; MacKinnon, 2008; Winship and Morgan, 1999). For example, omitted variable bias is the term used in the social sciences, while epidemiology and medicine call this confounder bias.

Holland (1988) has described a solution to estimate the causal effect of M on Y using an instrumental variables approach to estimating the β path based on assumptions of additivity, linear, and constant effects. A classic reference on the instrumental variable method is Angrist et al. (1996) who investigated the effect of Vietnam War service on health with random selection in the draft as the independent variable, serving in

Vietnam as the mediating variable, and health as the dependent variable. In the instrumental variable model, random selection in the draft (X) was used to predict serving in Vietnam (M), and the predicted values of war service were used to predict Y. Several assumptions required for the b path to have a causal interpretation often make it difficult to successfully apply instrumental variable methods (MacKinnon, 2008; Shadish et al., 2002). One assumption is that randomization of X leads to changes in M such that the stronger the relation of X to M the better the instrument; the ideal instrument has a correlation of one for X with M, which makes X indistinguishable from M. Because M can be considered randomized from its prediction by X, the influence of any omitted variable on the relation of M to Y is removed. A second important assumption, the exclusion restriction, is that M completely mediates the effect of X on Y such that when M is considered there is no relationship between X and Y. Complete mediation, however, may be unrealistic with real data from many research areas. The assumptions for the instrumental variable approach for mediation analysis were clarified and extended by Sobel (2008).

Another important method to address limitations of the mediation model is based on the classification of different possible response patterns for how X affects M and M affects Y. In principal stratification approaches, subsets of persons are specified based on their true relation for how M and Y could change in response to treatment X or if no treatment is received. For example, in a two-group treatment versus control study, there are four different types of hypothetical responses across X to M to Y as described by Jo (2008): (1) never-improvers or people whose mediator would not improve if they were in either the treatment or the control group; (2) forward-improvers, people whose mediator would improve only if they received the treatment; (3) backward-improvers, people whose mediator would improve only if they were in the control group; and (4) always-improvers, people whose mediator would improve if they were in either treatment group. These four types of people are determined outside the experiment so their classification is independent of their experimental assignment and as a result the omitted variables that confound the M to Y relation are ignorable. In most studies using principal stratification, a monotonicity assumption is made such that there are no participants for whom the mediator would improve for participants in the control condition because they are unexposed to the treatment strategies to improve the mediator. Given the three possible stratifications, the indirect effect is estimated by comparing means within and between these stratifications (Frangakis and Rubin, 2002; Jo, 2008). In these models, covariates often are used to provide information about the stratifications to identify parameters in the model, including propensity score methods to help define stratifications (Jo et al., 2011; Stuart et al., 2008).

The counterfactual interpretation of the mediation model has led to an important distinction between controlled and natural effects. Controlled effects are effects fixed to certain values, and natural effects are effects at observed or natural values obtained by research participants (Pearl, 2001, 2012; Robins and Greenland, 1992). Research questions may focus on a controlled effect such an effect that occurs when changing from no intervention to an intervention condition. There is no direct control of the mediator in most research studies so it is necessary to estimate effects at the natural value of the mediator. As a result, the natural indirect effect is the indirect effect at the value of M that the participant would have had if that participant was in the control condition and not exposed to an intervention. For the case of ordinary least squares regression, the controlled and natural direct effects are equivalent and provide a causal estimate of the indirect effect under the assumption of sequential ignorability (Imai et al., 2010; Pearl, 2001). For nonlinear models, such as logistic regression, the controlled and natural effects may differ at different values of variables in the model. Several alternative approaches are available to evaluate direct and indirect effects in nonlinear models, including a general mediation formula that is applicable across statistical models (Pearl, 2010).

Recent work has provided methods to evaluate the sensitivity of research results to violation of model assumptions, such as sequential ignorability. Sensitivity analyses for measurement error may be conducted by changing values of the error variance in a structural equation model and reestimating model estimates (MacKinnon, 2008). One way to investigate the sensitivity of model results to omitted variables is to assess how large a confounder effect on the M to Y relation must be to invalidate conclusions about mediation (Frank, 2000; Li et al., 2007; Lin et al., 1998; Rosenbaum, 2002). Another way to conduct sensitivity analyses for mediation would be to systematically increase the correlation between the errors in eqns [2] and [3], and evaluate how much the indirect effect estimates change when omitted variables related to both X and M would affect the results as described in Imai et al. (2010). VanderWeele (2008, 2010) has formalized methods to probe bias in mediation relations based on two parameters. One parameter corresponds to the relation of an unobserved binary confounder to Y. The second parameter corresponds to the difference in prevalence of the confounder variable, U, for people with the same value of M in the treatment and control groups. The extent to which a confounder affects the indirect effect estimate can be obtained by subtracting the biased value from the estimate of the indirect effect.

Historically, the method used to identify mediating processes is a program of experimental research designs in which each experiment provides increasing evidence to support a mediation relation. It is rare that one or even a few experiments provide enough information to demonstrate a true mediation relation (MacKinnon, 2008; Mark, 1986; West and Aiken, 1997). There are several experimental designs to assess mediation (MacKinnon, 2008; MacKinnon et al., 2010). The blockage design consists of an intervention to block the mediation process so that a relation observed in the usual condition, but not in the blockage condition, supports a mediating process. In an enhancement design, an experimental condition is designed to enhance the mediation process so that participants in this group would experience the greatest mediated effect. Another type of experimental design that has received more attention recently is the double randomization design, which uses one randomized study to evaluate the X to M relation and a second randomized study is used to evaluate the M to Y relation adjusting for X (MacKinnon, 2008; MacKinnon et al., 2010; Spencer et al., 2005). Other experimental designs focus on testing the consistency and specificity of mediation relations across different contexts, subgroups, and

measures of the mediating and outcome variables (MacKinnon et al., 2010). Even in experimental designs, estimation of the mediated effect is important. New developments in causal inference address how designs such as those described thus far may be combined with modern causal methods to obtain more accurate evidence for indirect effects (Imai et al., 2013). In particular, Imai et al. (2013) described several designs to overcome the sequential ignorability assumption.

More Complicated Mediation Models

The single mediator model is easily expanded to include a chain of mediating variables. In fact, most mediating variables are actually part of longer theoretical mediational chain (Cook and Campbell, 1979). For example, it is possible to measure each of the four constructs in a theoretical chain from exposure to a prevention program, to comprehension of the program, to short-term attitude change, to change in social norms, and to change in the dependent variable. Typically, researchers measure an overall social norms mediator rather than all mediators in the chain, even though a more detailed chain is theorized. It is a primary task of a mediation study to specify the chain of mediation to be examined, including mediating variables that are not so close theoretically to X and Y that they are the same variable as X and Y.

Longitudinal data provide evidence for temporal relations among variables. More detailed evidence for mediation can be obtained when X, M, and Y are measured repeatedly. For example, evidence for temporal relations among variables may be obtained by demonstrating that change in the mediator precedes and is related to subsequent change in the dependent variable (Cheong et al., 2003; Cole and Maxwell, 2003; MacKinnon, 2008). Longitudinal data also allow researchers to investigate mediation for within-person changes as well as between-person differences. For example, mediation can be modeled as X causes changes in M between baseline and the first follow-up, and the change in M between baseline and the first follow-up can be used to predict change in Y between the second and third follow-up, providing longitudinal evidence for mediation. The planning of longitudinal studies of mediation have the same challenges as other longitudinal studies, especially the determination of the optimal timing of when variables are related to each other and how to measure variables so that they have the best chance to detect these temporal relations. There are several different types of longitudinal models, including autoregressive models for relations between waves of measurement, with patterns consistent with measures at earlier times predicting a mediator at a later time that then predicts an outcome variable at a later time. Latent growth curve methods model growth in variables over time and relate the growth over time in the mediator and outcome. Latent change score models specify change models between waves and are particularly useful for modeling change at earlier waves on change at later waves. Another important longitudinal modeling approach attempts to classify people based on their pattern of change over time into patterns that are consistent or inconsistent with a mediation process (von Eye et al., 2009). Other approaches attempt to relate variables in the mediation model in continuous time.

Models with both mediators and moderators are often relevant in many research areas. For example, a mediation process may differ for males and females or may differ across ages. Models that combine moderation and mediation investigate the mediation process as well as differences in the process across these groups. The first moderation and mediation model would include the interaction between X and M in the eqn [2] such that the relation of M to Y differs across levels of Y. This interaction suggests that the mediated effect is different at different values of M and is an important interaction that can be routinely tested using the X and M interaction in eqn [2]. Other more complicated models with moderation and mediation are possible as well.

The single mediator methods can be extended for multiple mediators and multiple outcomes with correspondingly more mediated effects (Bollen, 1987). Multiple mediator models are justified because most independent variables have effects through multiple mediating processes. The true causal relationships are difficult to disentangle in this model because of the number of alternative relationships among variables. One solution to the problems inherent in the causal interpretation of more complex, as well as single mediator models, is to view the identification of mediating variables as a sustained research effort requiring a variety of experimental and nonexperimental approaches to identify mediating variables. The analysis of multiple mediators in one study informs the design of randomized experiments to contrast alternative mediating variables, leading to a refined understanding of mediating processes (MacKinnon, 2008; West and Aiken, 1997). Meta-analytical studies provide information about the consistency of mediating variable effects across many situations (Cook et al., 1992). Furthermore, the identification of mediating variables requires examination of additional sources, including ethnographic, historical, and clinical information (Cronbach, 1982).

Future Directions

Mediating variables will continue to play a major role in the social and behavioral sciences because of the need to understand how and why variables are related. In particular, the practical and theoretical benefits of mediating variables in prevention and treatment research should guide the development of effective interventions. Investigators will endeavor to find the information needed for the further application of detailed causal models outlined by Rubin (1974) and Pearl (2010) and related approaches to mediating variable models. Likely these causal inference approaches will be applied to more complicated mediation models, including experimental designs to investigate mediation. Accurate point and interval estimators of mediated effects will continue to be developed for various statistical methods, including categorical and longitudinal models. In addition to statistical approaches, sustained study of mediating variables will include information from a variety of sources, including history, journalism, and clinical experience. Such comprehensive efforts are necessary to determine whether a variable is truly intermediate in the causal sequence between two other variables.

Mediation, Arbitration, and Alternative Dispute Resolution (ADR)

Carrie J Menkel-Meadow, University of California, Irvine, CA, USA

Abstract

This article defines and describes modern processes of dispute resolution beyond court adjudication, including negotiation, mediation (facilitated negotiation), arbitration (decisions by party chosen private dispute resolvers), and a variety of new hybrid forms of dispute resolution (e.g., med-arb, summary jury trials, public policy consensus building) that are used in both public and private disputes. The article reviews the history and theory behind these processes, outlining quantitative and qualitative reasons for their use, and then reviews a variety of controversies associated with their use, including the privatization of dispute resolution, difficulty in evaluating their effectiveness, and power imbalances in their use. The aspirational qualities of process pluralism (peaceful, better quality, and consent-based resolution of conflicts) are contrasted to the realities of their use and cooptation in some contexts, such as when powerful private and public parties dictate the form that dispute resolution takes, without true party consent.

Mediation, arbitration, and alternative dispute resolution (ADR) are processes used to resolve disputes, either within or outside the formal legal system, without adjudication or decision by a judge. More recently, the terms 'appropriate dispute resolution' and 'process pluralism' have been used to express the idea that different kinds of disputes, variable by subject matter type, parties involved, or location of the dispute or transaction, may require different kinds of processes – no one legal or informal dispute process can serve for all human disputing. Mediation is a process in which a third party (usually neutral and unbiased) facilitates a negotiated consensual agreement among parties, without rendering a formal decision. In arbitration, a single third party or a panel of arbitrators, most often chosen by the parties themselves, renders a decision, in terms less formal than a court, but often with a written award. ADR includes a variety of hybrid processes built on the basic processes of negotiation, mediation, and arbitration, now including med-arb, minitrials, summary jury/judge trials, and early neutral evaluation, which vary in providing opportunities for settlement of cases, advisory opinions, or decisions in both public (court-annexed) and private settings. This article defines the basic ADR terms and reviews the theory, history, controversies, and future of ADR processes.

As noted below, the full panoply of processes denominated under the rubric of ADR now includes a variety of primary and hybrid processes, with elements of dyadic negotiation, facilitative, advisory, and decisional action by a wide variety of third party neutrals, sometimes combined with each other to create new formats of dispute processing (*see* Negotiation and Bargaining: Role of Lawyers; International Arbitration; Litigation; Courts and Adjudication; Disputes, Social Construction and Transformation of; Legal Systems: Private; Lex Mercatoria; Legal Pluralism; Lawyers: Social Organization of the Profession; Judges; Paralawyers: Other Legal Occupations).

Definitions and Types of Processes

In an era characterized by a wide variety of processes for resolving disputes among individuals, organizations, and nations, process pluralism has become the norm in both formal disputing systems, like legal systems and courts, and in more informal, private settings, as in private contracts and transactions, family disputes, and internal organizational grievance systems. There are a number of factors that delimit the kinds of processes which parties may choose or may be ordered to use under rules of law, court, or contract.

The primary processes consist of individual action (self-help, avoidance), dyadic bargaining (negotiation), third-party-facilitated approaches (mediation), and third-party decisional formats (arbitration and adjudication). Hybrid or secondary processes combine elements of these processes and include med-arb (facilitated negotiation followed by decision), minitrials (shortened evidentiary proceedings followed by negotiation), summary jury/judge trials (use of mock jurors or judges to hear evidence and issue advisory verdicts to assist in negotiation, often conducted within the formal court system), and early neutral evaluation (third parties, usually lawyers or other experts, who hear arguments and evidence, and advise about the issues or values of the dispute, for purposes of facilitating a settlement or structuring the dispute process). Increasing judicial involvement in dispute settlement suggests that judicial, and often mandatory, settlement conferences are another form of hybrid dispute mechanism. Retired judges provide a hybrid form of arbitration or adjudication in private 'rent-a-judge' schemes that are sometimes authorized by particular states (in the United States, e.g., California provides for this process in its state constitution). In other countries, it is becoming more common for retired judges to offer these services, usually for private fees.

Dispute processes are also characterized by the extent to which they are voluntary and consensual (whether in predispute contract agreements, ADR *ex ante*, or voluntarily undertaken after the dispute ripens, ADR *ex post*), or whether they are mandated (by a predispute contract commitment) or by court rule or referral. The ideology that contributed to the founding of modern mediation urges that mediation should be entered into voluntarily and all agreements should be arrived at consensually (Menkel-Meadow, 1995a). Nevertheless, as courts have increasingly sought to 'manage' or reduce their caseloads and have looked to ADR processes as a means of diverting cases to other fora, even mediation may be mandated,

 http://dx.doi.org/10.1016/B978-0-08-097086-8.86083-3

although it is usually participation in, not substantive agreement, that is required.

The taxonomy of different dispute processes also differentiates between binding and nonbinding processes. Arbitration, for example, can be structured either way. Under some contractual and statutory schemes (such as the American Federal Arbitration Act), decisions by private arbitrators are final and binding on the parties, and subject to very limited court review, including only such claims as fraud, corruption of the arbitrator, or, in a few jurisdictions, serious errors of law or extreme 'miscarriages of justice.' Nonbinding processes, including nonbinding decisions in some arbitrations, allow appeals or follow-through to other processes, such as mediation or full trial. Many court-annexed arbitration programs, for example, allow a *de novo* trial following an arbitration if one party seeks it, often having to post a bond or deposit for costs. The process of mediation itself is nonbinding; as it is a consensual process, a party may exit at any time. On the other hand, once an agreement in mediation is reached, a binding contract may be signed, which will be enforceable in a court of law.

Finally, dispute processes are often subject to different requirements depending on whether they are used in private settings (by contract, in employment or other organizational settings) or in public arenas such as courts. Court-related or court-annexed ADR programs, now encompassing the full panoply of dispute processes, may be subject to greater legal regulation, including selection, training, and credentialing of the arbitrators or mediators, ethics, confidentiality, and conflicts of interest rules, as well as providing for greater immunity from legal liability.

ADR processes are often differentiated from each other by the degree of control the third party neutral has over the process (the rules of proceedings), the substance (decision, advice, or facilitation), and the formality of the proceeding (whether held in private or public settings, with or without formal rules of evidence, informal separate meetings, or caucuses with the parties, and with or without participation of more than the principal disputants). ADR processes are being applied increasingly to diverse kinds of conflicts, disputes, and transactions, some requiring expertise in the subject matter (such as scientific and policy disputes) and spawning new hybrid processes such as consensus building, which engage multiple parties in complex, multi-issue problem solving and draw on negotiation, mediation, and other nonadjudicative processes (Susskind et al., 1999).

Although there have been efforts to develop taxonomies or predictive factors for assignment of particular case types to particular processes (and some courts assign or prohibit certain case types in some categories of dispute resolution), for the most part these efforts 'to fit the forum to the fuss' (Sander and Goldberg, 1994) have been unsuccessful. Amenability of different cases to different processes just as often depends on the personalities of the disputants, parties, lawyers, and third party neutrals as on any particular case type characteristic.

Theory and History of ADR

The modern growth of arbitration, mediation, and other ADR processes can be attributed to at least two different animating concerns. On the one hand, scholars, practitioners, consumers, and advocates for justice in the 1960s and 1970s noted the lack of responsiveness of the formal judicial system and sought better 'quality' processes and outcomes for members of society seeking to resolve disputes with each other, with the government, or with private organizations. This strand of concern with the quality of dispute resolution processes sought deprofessionalization of judicial processes (a reduction of the lawyer monopoly over dispute representation), and greater access to more locally based institutions such as neighborhood justice centers, which used community members, as well as those with expertise in particular problems, with the hope of generating greater party participation in dispute resolution processes (Merry and Milner, 1993). Others sought better outcomes than those commonly provided by the formal justice system, which tend toward the binary, polarized results of litigation in which one party is declared a loser, while the other is, at least nominally, a winner. More flexible and party-controlled processes were believed to deliver the possibility of more creative, Pareto-optimal solutions which are geared to joint outcomes, reduction of harm or waste to as many parties as possible, improvement of long-term relationships, and greater responsiveness to the underlying needs and interests of the parties (Menkel-Meadow, 1984; Fisher et al., 1991). Some legal and ADR processes (like arbitration) are rule based, but other forms of ADR (negotiation and mediation) are thought to provide individualized solutions to problems, rather than generalized notions of 'justice.'

A second strand of argument contributing to the development of ADR was, however, more quantitatively or efficiency based. Judicial officers, including those at the top of the American and English justice systems, argued that the excessive cost and delay in the litigation system required devices that would divert cases from court and reduce case backlog, as well as provide other and more efficient ways of providing access to justice (Burger, 1976; Woolf, 1996). This efficiency-based impetus behind ADR encouraged both court-mandated programs (like court-annexed arbitration for cases with lower economic stakes) and contractual requirements to arbitrate any and all disputes arising from services and products (provided in banking, health care, consumer, securities, educational, and communication-based industries).

Modern ADR structures are related only loosely to their historical antecedents. In many countries, arbitration had its origins in private commercial arbitrations, outside of the formal court structure, and it was used principally by merchants when disputing with each other (Dezalay and Garth, 1996). In the United States, labor arbitration developed to secure 'labor peace,' as well as to develop a specialized substantive 'law of the shop floor' (Fuller, 1963).

Early use of mediation or conciliation occurred in some courts and communities seeking both to reduce caseloads and to provide more consensual agreements in ethnically or religiously homogeneous areas (Auerbach, 1983). Indeed, mediation and other consensually based processes are thought to work best in regimes where there are shared values, whether based on common ethnicity or communitarian or political values (Shapiro, 1981). In Asian and other nations with more communitarian and harmony-based cultures (as contrasted to more litigative or individualistic cultures), mediation is often

the preferred form of dispute resolution, but it too has been used for system or political regime purposes beyond resolving the disputes of the parties (Lubman, 1967). Thus, most political regimes have had to deal with both public and private forms of dispute resolution that often supplement, but sometimes challenge or compete with, each other. Mediation is now promoted in transborder disputes, where the applicable law may not be clear (see European Directive, 2008/52/EC; Steffek, 2011).

The introduction or revival of multiple forms of dispute resolution (including mediation, arbitration, ombuds, and conciliation) within the legal system probably dates to the 1976 conference on the "Causes of Popular Dissatisfaction with the Administration of Justice." The idea of a 'multidoor courthouse' was suggested in order to meet both the caseload needs of the judicial system and the 'quality of justice' needs of consumers in a rapidly growing arena of legally and culturally cognizable claims (Sander, 1976). More deeply contextualized study of the social transformation of conflicts into legally cognizable claims by a community of sociolegal scholars (Felstiner et al., 1980–1981), drawing on anthropological, sociological, political, and psychological insights, also contributed to the theoretical, as well as practical, significance of pluralism in disputing. More recently, dispute resolution has been championed by those who focus on facilitating deliberative democracy in the larger polity as well (Menkel-Meadow, 2011, 2012).

Applications

Each of the ADR processes has its own logic, purposes, and jurisprudential justifications. Mediation and conciliation are often used to improve communications between parties, especially those with preexisting relationships, to 'reorient the parties to each other' (Fuller, 1971) and to develop future oriented solutions to broadly defined conflicts. Arbitration, on the other hand, being more like adjudication (Fuller, 1963, 1978) is used more often to resolve definitively a concrete dispute about an event that has transpired and requires fact finding, interpretation of contractual terms, or application of legal principles.

These basic forms have been adapted to a number of subject areas and dispute sites. As regular use of these formats of dispute resolution becomes more common, mediation seems to be overtaking arbitration as a preferred method of dispute resolution (because of the ideology of party self-determination and the flexibility of agreements). Arbitration, still most commonly used in labor disputes, is now the method of choice in form contracts signed by consumers as well as merchants. In the United States, mandatory predispute contractual commitments to arbitrate a wide variety of consumer, health care, securities, and employment disputes have been sustained by the US Supreme Court against claims these clauses violate due process or other constitutional rights to trial for disputes. Similarly, thus far many European courts have held that assignment to some form of ADR (mediation usually, but in some cases, arbitration as well) does not violate Art. 6 of the European Convention on Human Rights, granting basic hearing rights for human rights cases. Arbitration has, thus far, been the mode of choice for resolving international commercial, investment, and trade disputes, such as in the public law settings of the World Trade Organization (WTO), the General Agreement on Tariffs and Trade (GATT), and the International Center for the Settlement of Investment Disputes (ICSID), and the more private international law settings of the International Chamber of Commerce or the London Court of Arbitration. Arbitration has also been deployed in new forms of disputes developing under both domestic and international intellectual property regimes. Various forms of mediation and arbitration are also increasingly being used to resolve transnational disputes of various kinds (political, economic, natural resource allocation, and ethnic violence) and are employed by international organizations such as the United Nations and the Organization of American States, as well as multinational trade and treaty groups (NAFTA, the European Union, and Mercosur) and nongovernmental organizations in human rights and other issue-related disputes (Greenberg et al., 2000). Arbitration (and occasionally other forms of dispute resolution) is now commonly used in sports disputes, such as for the Olympics and FIFA (the International Federation for Football (Soccer)), with a special tribunal to administer such dispute resolution, located in Lausanne, Switzerland.

Beginning in the United States, but now in use internationally, mass injury (class action) cases, both involving personal and property damages, have been allocated to ADR claims facilities, utilizing both arbitral and mediative forms of individual case processing. In legal regimes all over the world, family disputes are increasingly assigned to mediative processes, both for child custody and for support and maintenance issues. In many nations, this growth in family mediation has spurred the development of a new profession of mediators, drawn from social work or psychology, who sometimes compete with lawyers both in private practice and as court officers (Palmer and Roberts, 1998).

In many jurisdictions, such as the United States, the United Kingdom, Italy, and the Netherlands, among others, some form of referral to ADR is now required before a case may be tried. Increasingly, however, parties to particularly complex disputes, such as environmental, mass torts, or governmental budgeting, may convene their own ADR processes, with a third party neutral facilitating a new form of public participatory process that combines negotiation, fact-finding, mediation, and joint problem solving. Such consensus building processes have also been applied to the administrative tribunal processes of both rule-making and administrative adjudication in a new process called 'reg-neg' (negotiated rule-making or regulation).

Although ADR has been considered, until quite recently, principally an American alternative to courts, the use of ADR is spreading slowly around the world, being used to relieve court congestion, to provide expertise in various subject matter disputes (e.g., construction, labor matters, family law), to build transnational dispute systems for economic, human rights, and political issues, and to offer alternative justice systems where there is distrust of existing judicial institutions. Increasingly, many national legal systems (e.g., England and Scotland, Italy, Argentina) require some effort at ADR (usually mediation) before a case may proceed to trial in civil cases. There is increased education and training for dispute resolution professionals, including both lawyers and nonlawyers (social

workers, psychologists, accountants, engineers, and architects) in a wide variety of settings, both within universities and in trade schools and other programs. The use of ADR across borders and cultures raises complex questions about intercultural negotiations (Salacuse, 1998) and multijurisdictional sources of law or other principles for dispute resolution.

Controversies

The use of mediation, arbitration, and ADR processes, in lieu of more traditional adjudication, has not been without its controversies, which are reviewed briefly in this section (Menkel-Meadow, 1997).

Privatization of Jurisprudence

With the increased use of negotiated settlements, mediation, and private arbitration, there has been concern that fewer and fewer cases will be available in the public arena for the making of precedent (Fiss, 1984), and debate about and creation of rules and political values for the larger community will suffer (Luban, 1995). As settlements are conducted in private and often have confidentiality or secrecy clauses attached to them, others will not learn about wrongs committed by defendants, and information that might otherwise be discoverable will be shielded from public view. Settlements may be based on nonlegal criteria, threatening compliance with and enforcement of law. Claims are more likely to be individualized than collectivized.

Whether there is more privatization or secrecy in the settlement of legal disputes than at some previous time itself remains a subject of controversy as empirical studies document relatively stable rates of nonjudicial case terminations (at over 90 percent in many jurisdictions and across all types of disputes) (Kritzer, 1991).

Related concerns about the privatization of the judicial system include increased indirect state intervention in the affairs of the citizenry through more disputing institutions, at the same time that the exit of wealthier litigants gives them less stake in the quality and financing of public justice systems (Abel, 1982). The debate centers on whether dispute resolution systems can serve simultaneously the private interests of disputants before them and the polity's need for the articulation of publicly enforced norms and values (Menkel-Meadow, 1995b).

Inequalities of Bargaining Power

A number of critics have suggested that less powerful members of society, particularly those subordinated by race, ethnicity, class, or gender, will be disadvantaged disproportionately in ADR processes where there are no judges, formal rules, or, in some cases, legal representatives to protect the parties and advise them of their legal entitlements (Delgado et al., 1985; Grillo, 1990–1991). Responses from ADR theorists suggest that there is little empirical evidence that less advantaged individuals or groups necessarily fare better in the formal justice system, and that sophisticated mediators and arbitrators are indeed sensitive to power imbalances and can be trained to 'correct' for them without endangering their neutrality in the ADR process. Many private ADR organizations have begun developing standards for good practices and due process protocols to protect the parties and ensure the integrity of the process.

Evaluation and Empirical Verification of Effectiveness

There are few robust research findings with respect to the effectiveness of ADR in meeting its claimed advantages. Recent findings from studies of ADR in the American federal courts have been contradictory about whether arbitration, mediation, and some forms of early neutral evaluation decrease case processing time or costs, either for the parties or for the system. Preliminary studies from England demonstrate low usage of mediation schemes (Genn, 1999). Yet studies continue to demonstrate high satisfaction rates among users of arbitration and mediation programs (MacCoun et al., 1992), and higher compliance rates with mediated outcomes than traditional adjudication (McEwen and Maiman, 1986). In light of the variation in ADR programs, it is too early for there to be sufficient databases for accurate comparisons between processes (Menkel-Meadow, 2010).

Distortions and Deformations of ADR Processes

Within the nascent ADR profession there is concern that the early animating ideologies of ADR are being distorted by their assimilation into the conventional justice system. Within a movement that sought to deprofessionalize conflict resolution, there are now competing professional claims for control of standards, ethics, credentialing, and quality control between lawyers and nonlawyers. Processes like mediation that were conceived as voluntary and consensual are now being mandated by court rules and contracts. Processes that were supposed to be creative, flexible, and facilitative are becoming more rigid, rule and law based, and judicialized as more common law is created by courts about ADR, and more laws are passed by legislatures. The overall concern is that a set of processes developed to be alternative to the traditional judicial system are themselves being coopted within the traditional judicial process with its overwhelming adversary culture. Policy makers and practitioners in the field are concerned about whether a private market in ADR is good for 'disciplining' and competing with the public justice system or whether, on the other hand, there will be insufficient accountability within a private market of dispute resolution.

The Future of ADR

There is no question that the use of a variety of different processes to resolve individual, organizational, governmental, political, and international problems is continuing to expand. New hybrid forms of ADR (as in mediation on the Internet (Katsh and Rifkin, 2001) and public policy mediation and consensus building) are developing to help resolve new problems, with greater participation by more parties. Large organizations are creating their own internal dispute resolution systems. There are clear trends in favor of mediation and arbitration in the international arena, where globalization of

enterprises and governmental interests require creative and simple processes that are not overly attached to any one jurisdiction's substantive law. These systems can promote goals of efficiency, fairness, clarity, and legitimacy, particularly in regimes with underdeveloped formal legal systems. It is also clear that there is competition over who will control such processes, and which processes will dominate in which spheres of human disputing and deal-making. The likely result is that the creative pluralism and flexibility of ADR will be subject increasingly to its own forms of formality and regulation in an effort to keep its promises of efficiency, participation, better quality outcomes, and justice.

Abstract

The goal of causal mediation analysis is to investigate the extent to which the causal effect of a 'treatment' variable on an outcome variable is propagated through a third (or more) variable – the mediator of interest. The focus is to partition the total effect into an indirect effect and a direct effect. After defining various relevant causal effects using potential outcomes, four approaches of causal mediation analysis are addressed, including linear structural equation models, linear counterfactual models with potential errors, marginal structural models, and principal stratification.

The goal of causal mediation analysis is to investigate the extent to which the causal effect of a 'treatment' variable Z (the cause of interest) on an outcome variable Y is propagated through a third (or more) variable M – the mediator of interest (see Figure 1). The focus is not to estimate the total effect of treatment Z on outcome Y, but to partition the total effect into an indirect effect mediated by M and a direct effect not mediated by M. (Note that the direct and indirect effects are relative terms, depending on the choice of the mediator(s) of interest.) That is, it is the underlying causal mechanism (the causal pathways from Z to Y), rather than the simple overall causal effect of Z on Y, that is of primary interest.

Causal mediation analysis has been widely practiced in many social, behavioral, and other scientific disciplines, such as psychology, sociology, political science, and epidemiology (see MacKinnon, 2008). Moreover, mediation is the basis of causal inference in more complicated longitudinal and network settings. Thus, discussions in this article also have direct implications for those settings.

As an example, Rossi et al. (1980) conducted a randomized experiment to examine whether providing monetary support to recently released ex-convicts could reduce the rate of recidivism. Thousands of ex-convicts were randomized into a treatment group in which subjects either received money transfers ($Z=1$) or assigned to a control group without monetary support ($Z=0$). (This is a simplified description of the original experiment.) The outcome Y was whether the ex-convict got rearrested ($Y=1$) or not ($Y=0$). The authors found no total effect of money transfers on the rearrest rate in the experiment. In an attempt to uncover the causal mechanism that led to this zero total effect, Rossi et al. introduced a mediator – the number of hours each ex-convict worked per week after release. Their mediation analysis suggested that the supposed negative direct effect of money transfers on the rearrest rate had been canceled out by a positive indirect effect via the mediator. A (over)simplified version of the authors' argument was as follows. On the one hand, many ex-convicts get reinvolved in illegal (money-generating) activities soon after release because of financial difficulty. Thus, giving them money would reduce the incentive for them to reengage in illegal activities, which would lower the rearrest rate (a negative direct effect). On the other hand, money transfer would also reduce the incentive for them to work legally, resulting in fewer weekly working hours (M). Less time spent in legal employment means weaker social regulations, which would in turn increase recidivism (a counterbalancing positive effect). However, this argument ignited a heated debate on the validity of the methods used for mediation analysis (see Zeisel, 1982a,b; Rossi et al., 1982; Smith, 2013). The mediation framework of this experiment is used in this article in various places as an example.

Figure 1 Three variable path diagram with mediator *M*.

Formal Definitions of Causal Effects

Holland (1988) and Robins and Greenland (1992) use the notation of potential outcomes (or counterfactuals) to formally define various causal effects relevant to mediation. Unless otherwise stated, the treatment, mediator, and outcome are assumed throughout to be either binary or continuous (this can be easily modified to accommodate more general cases). Let $M_i(z)$ denote the mediator value subject (or respondent) i would take on if i, possibly contrary to fact, received treatment level z. $Y_i(z, m)$ is the outcome value i would take on if i were assigned treatment level z and mediator level m. $Y_i[z, M_i(z)]$ is the outcome of i under treatment z, that is, $Y_i[z, M_i(z)] \equiv Y_i(z)$. $Y_i[z, M_i(z')]$ denotes i's outcome if i received treatment z while the mediator was fixed at the level which i would 'naturally' take on under treatment level z' different from z. For example, in the recidivism experiment, $M_i(1)$ is the weekly hours ex-convict i would work after release if he or she received money transfers; $Y_i(0, 40)$ is the outcome status of i (irrespective of being rearrested or not) if i did not receive money transfers and was 'forced' to work 40 h per week; $Y_i[1, M_i(1)]$ is i's outcome if the particular recently released ex-convict received money transfers; $Y_i[0, M_i(1)]$ is i's outcome if the individual did not receive money transfers and was 'forced' to work $M_i(1)$ hours per week, where $M_i(1)$ is the number of hours i would 'voluntarily' work if receiving money transfers. It is assumed throughout that the potential

outcomes of i depend only on the treatment status of i, *not* on the treatment status of any other subject j ($j \neq i$). Rubin (1980) calls this the stable unit treatment value assumption (SUTVA), which rules out between-subject interference.

In contrast, let Z_i, M_i, Y_i denote the actually realized values of subject i's treatment, mediator, and outcome, respectively, and $\mathbf{X}_i$ a vector of observed pretreatment covariates. Clearly, for binary treatment, $M_i = M_i(1) \times Z_i + M_i(1) \times (1 - Z_i)$, and $Y_i = Y_i[1, M_i(1)] \times Z_i + Y_i[0, M_i(0)] \times (1 - Z_i)$.

With potential outcomes, various causal effects at both the subject/unit and aggregate levels can be defined. For each subject i,

unit effect of Z on M:

$$M_i(z) - M_i(z') \qquad [1a]$$

(average) effect of Z on M:

$$\mathrm{E}\{M(z) - M(z')|\mathbf{X}\} \qquad [1b]$$

where the aggregate effect ([1b]) is obtained by averaging the unit effect ([1a]) over some subpopulation/subgroup defined by covariates $\mathbf{X}_i$ (subscript i is suppressed for all causal effects at the aggregate level for simplicity); If it is the average effect for the whole population/group that is of interest, the conditioning part (on $\mathbf{X}$) can be removed;

unit controlled direct effect (of Z on Y):

$$Y_i(z, m) - Y_i(z', m) \qquad [2a]$$

controlled direct effect (of Z on Y):

$$\mathrm{E}\{Y(z, m) - Y(z', m)|\mathbf{X}\} \qquad [2b]$$

unit controlled effect of M on Y:

$$Y_i(z, m) - Y_i(z, m') \qquad [3a]$$

controlled effect of M on Y:

$$\mathrm{E}\{Y(z, m) - Y(z, m')|\mathbf{X}\} \qquad [3b]$$

unit total effect (of Z on Y):

$$Y_i[z, M_i(z)] - Y_i[z', M_i(z')] \qquad [4a]$$

total effect (of Z on Y):

$$\mathrm{E}\{Y[z, M(z)] - Y[z', M(z')]|\mathbf{X}\} \qquad [4b]$$

unit pure direct effect (of Z on Y):

$$Y_i[z, M_i(z')] - Y_i[z', M_i(z')] \qquad [5a]$$

pure direct effect (of Z on Y):

$$\mathrm{E}\{Y[z, M(z')] - Y[z', M(z')]|\mathbf{X}\} \qquad [5b]$$

unit total indirect effect (of Z on Y):

$$Y_i[z, M_i(z)] - Y_i[z, M_i(z')] \qquad [6a]$$

total indirect effect (of Z on Y):

$$\mathrm{E}\{Y[z, M(z)] - Y[z, M(z')]|\mathbf{X}\} \qquad [6b]$$

For example, in the recidivism experiment, the unit controlled direct effect $Y_i(1, 30) - Y_i(0, 30)$ is the effect of receiving money ($z = 1$) versus not receiving money ($z = 0$) on rearrest for the *same* subject i, given that the mediator (weekly working hours) is fixed at 30. In contrast, the unit pure direct effect $Y_i[1, M_i(0)] - Y_i[0, M_i(0)]$ is the effect of receiving money versus not receiving on rearrest for subject i, given that the mediator is fixed at $M_i(0)$ – the weekly hours i would 'voluntarily' work if i did not receive money ($z = 0$). Note that for the controlled direct effect (CDE), $E\{Y(1, 30) - Y(0, 30)\}$, the mediator is uniformly fixed at the *same* level – 30 h per week – for *all* subjects, while for the pure direct effect (PDE), $E\{Y[1, M(0)] - Y[0, M(0)]\}$, the mediator is set at a subject-specific level $M_i(0)$ which usually varies across subjects.

Several remarks are in order. First, all the causal effects defined above are comparisons between pairs of potential outcomes of the *same* subject. However, in most empirical cases, only one of the two potential outcomes in comparison is observed for each subject. As a result, the unit level effects in general cannot be obtained (see Bertrand and Mullainathan, 2003 for an exception) – this has been described as the fundamental problem of causal inference. Second, the total effect ([4b] or [4a]) can be decomposed into the sum of PDE ([5b] or [5a]) and the total indirect effect (TIE) ([6b] or [6a]). See Wang and Sobel (2013) for a comprehensive review of other ways to decompose the total effect. Third, in general, CDE ([2b] or [2a]) is not equal to PDE ([5b] or [5a]), and thus cannot be used in the decomposition. Fifth, Pearl (2001) renames ([5b]) as 'natural direct effect,' and many authors now use this name instead. At last, the controlled effects (([2a] or [2b]) and ([3a] or [3b])) are often of greater interest in cases where both the treatment and the mediator can be manipulated in practice, while the PDE ([5a] or [5b]) and TIE ([6a] or [6b]) are of greater interest when the mediator cannot be manipulated through intervention.

Approach One: Linear Structural Equation Models

Baron and Kenny (1986) popularized the use of linear structural equation models (LSEMs) to study mediation. A typical LSEM is specified as

$$M_i = \alpha_0 + \alpha_1 Z_i + \boldsymbol{\alpha}'\mathbf{X}_i + \varepsilon_i \qquad [7a]$$

$$Y_i = \beta_0 + \beta_1 Z_i + \beta_2 M_i + \boldsymbol{\beta}'\mathbf{X}_i + \eta_i \qquad [7b]$$

where the error terms satisfy $\mathrm{E}\{\varepsilon_i|Z_i, \mathbf{X}_i\} = 0$ and $\mathrm{E}\{\eta_i|Z_i, M_i, \mathbf{X}_i\} = 0$, and ε_i and η_i may or may not be correlated. The LSEM parameter α_1 is usually called the 'effect' of Z on M, β_1 the 'direct effect,' β_2 the 'effect' of M on Y, $\alpha_1\beta_2$ the 'indirect effect,' and $\beta_1 + \alpha_1\beta_2 \equiv \tau$ the 'total effect.'

However, Robins (1986) and Holland (1988) point out that, even if the LSEM ([7a] and [7b]) is correctly specified, these so-called 'effects' are in general not equal to their causal counterparts defined in the section 'Formal Definitions of Causal Effects' and thus cannot afford causal interpretations. For instance, with binary treatment Z, the LSEM parameter β_1, the so-called 'direct effect,' is equal to $\mathrm{E}\{Y|Z = 1, M = m, \mathbf{X} = \mathbf{x}\} - \mathrm{E}\{Y|Z = 0, M = m, \mathbf{X} = \mathbf{x}\}$. That is, the comparison is between two subpopulations/subgroups. The first includes those subjects with $\{Z = 1, M = m, \mathbf{X} = \mathbf{x}\}$, while the second includes those with $\{Z = 0, M = m, \mathbf{X} = \mathbf{x}\}$, and these two subgroups are generally not exchangeable. For example, in the recidivism experiment, the subgroup with $\{Z = 1, M = 30, \mathbf{X} = \mathbf{x}\}$ consists of ex-convicts who receive money

transfers and work 30 h week^{-1}, while the one with $\{Z=0, M=30, \mathbf{X}=\mathbf{x}\}$ includes those who do not receive money and work 30 h week^{-1}. These two subgroups may differ from each other systematically – e.g., those in the first subgroup could be on average poorer (or more diligent) than those in the second, as they, even though receive money transfers, still work the same number of hours as those in the second who do not receive money. Thus, such a comparison is problematic. In contrast, the causal counterpart, the CDE ([2b] and [2a]) or PDE ([5b] and [5a]), is defined by comparing each subject with him/herself. It then becomes clear that the LSEM parameters in general cannot be interpreted causally.

In order for the LSEM parameters to equal their causal counterparts, strong assumptions are needed:

$$Y_i(z,m), M_i(z) \perp Z_i | \mathbf{X}_i \qquad [8a]$$

$$Y_i(z,m) \perp M_i | Z_i, \mathbf{X}_i \qquad [8b]$$

Robins (1986) calls these the (sequential) ignorability assumptions. The substantive meaning of [8a] is that given covariates $\mathbf{X}_i$, treatment Z_i can be seen as randomly assigned; or, in observational contexts, $\mathbf{X}_i$ includes all confounders of both the *Z-Y* (treatment-outcome) and *Z-M* (treatment-mediator) relations. Condition [8b] means that given covariates $\mathbf{X}_i$ and treatment assignment Z_i, the mediator M_i behaves as if it is randomly assigned; or, $\mathbf{X}_i$ and Z_i include all confounders for the *M-Y* (mediator-outcome) relationship. If both [8a] and [8b] hold, the total effect ([4b]) $= \beta_1 + \alpha_1\beta_2 \equiv \tau$, the effect of Z on M ([1b]) $= \alpha_1$, the controlled effect of M on Y ([3b]) $= \beta_2$, CDE ([2b]) = PDE ([5b]) $= \beta_1$, and TIE ([6b]) $= \alpha_1\beta_2$.

For experimental studies in which only the treatment is randomized, [8a] automatically holds; however, [8b] in general does not hold unless $\mathbf{X}_i$ includes all confounders for the *M-Y* relationship. If [8a] holds but [8b] does not, as in the case of the recidivism experiment, and the LSEM ([7a] and [7b]) is employed, then only the 'total effect,' $\tau \equiv \beta_1 + \alpha_1\beta_2$, equals the total effect ([4b]), and the 'effect of Z on M' α_1 equals the effect of Z on M ([1b]), but the rest of the LSEM 'effects' do not equal their causal counterparts. (Note that as the outcome in the recidivism experiment is binary, logistic model is a better alternative to eqn [7b]; see VanderWeele and Vansteelandt, 2010 for details. However, this does not affect the argument made herein.) Thus, applying LSEM (or its variants) to those experiments in which only the treatment, but not the mediator, is randomized would generally give wrong and probably misleading results about the direct and indirect effects. Wang and Sobel (2013, p. 225) give a simulated example of such an experiment in which both the true direct and indirect effects are zero, but the correctly specified LSEM (with uncorrelated error terms ε_i and η_i) wrongly gives nonzero 'effects.'

There are two possible remedies. First, one could randomize both the treatment and mediator in an experiment. Randomizing the treatment solves the confounding problems for the *Z-M* and *Z-Y* relations, and randomizing the mediator removes confounding from the *M-Y* relation. Thus, sequential ignorability ([8a] and [8b]) is guaranteed to hold. Second, if the mediator cannot be randomized, one could collect information on as many *M-Y* confounders as possible, in the hope that these confounders included in $\mathbf{X}_i$ account for most of the *M-Y* confounding. In observational studies, even [8a] typically does not hold. In such cases, one should include into $\mathbf{X}_i$ all major confounders for not only the *Z-M*, *Z-Y*, but also the *M-Y* relations. Since one can never be sure if all the major confounders are included, sensitivity analysis is highly recommended (see VanderWeele, 2010).

Approach Two: Linear Counterfactual Models with Potential Errors

Holland (1988) and Sobel (2008) develop a linear counterfactual model (LCM) parallel to LSEM:

$$M_i(z) = \alpha_0^c + \alpha_1^c z + \boldsymbol{\alpha}_i^{c\prime\mathbf{X}} + \varepsilon_i(z) \qquad [9a]$$

$$Y_i(z,m) = \beta_0^c + \beta_1^c z + \beta_2^c m + \boldsymbol{\beta}_i^{c\prime\mathbf{X}} + \eta_i(z,m) \qquad [9b]$$

where $\mathrm{E}\{\varepsilon_i(z)|\mathbf{X}_i\} = 0$ and $\mathrm{E}\{\eta_i(z,m)|\mathbf{X}_i\} = 0$ for any fixed z and m; the superscript 'c' indicates these are parameters of a counterfactual model. There are several differences between the LCM ([9a] and [9b]) and the LSEM ([7a] and [7b]). First, the observed variables M_i and Y_i in the LSEM become potential outcomes in the LCM. Second, the observed treatment and mediator Z_i and M_i (as random variables) in the LSEM become 'fixed' variables z and m that can be conceptually manipulated. Third, the error terms ε_i and η_i in the LSEM turn into 'potential errors' $\varepsilon_i(z)$ and $\eta_i(z,m)$. It is straightforward to verify that α_1^c is the effect of Z on M ([1b]); β_1^c is the CDE ([2b]); β_2^c is the controlled effect of M on Y ([3b]). (Note that $\boldsymbol{\alpha}^c$ and $\boldsymbol{\beta}^c$ should not be given causal interpretation.)

In general, these LCM parameters cannot be identified, because not all potential outcomes $M_i(z)$ and $Y_i(z, m)$ can be observed for each subject i. However, if sequential ignorability ([8a] and [8b]) holds, it turns out that $\alpha_1^c = \alpha_1, \beta_1^c = \beta_1, \beta_2^c = \beta_2$, That is, the LCM parameters can be identified with the corresponding LSEM parameters. Moreover, the total effect ([4b]), denoted here by τ^c, can be shown to satisfy $\tau^c = (\beta_1^c + \alpha_1^c\beta_2^c) = (\beta_1 + \alpha_1\beta_2) \equiv \tau$; CDE ([2b]) = PDE ([5b]) $= \beta_1^c = \beta_1$, and TIE ([6b]) $= \alpha_1^c\beta_2^c = \alpha_1\beta_2$.

Because sequential ignorability ([8a] and [8b]) is very strong and cannot be met in most empirical settings, Holland (1988) instead assumes only [8a] and replaces [8b] with the following two assumptions:

$$\varepsilon_i(z) = \varepsilon_i, \eta_i(z,m) = \eta_i \quad \text{for all } z \text{ and } m \qquad [10]$$

$$\beta_1^c = 0, \quad \alpha_1^c \neq 0 \qquad [11]$$

If assumptions [8a], [10], and [11] hold, it can be shown that the LCM parameters satisfy $\tau^c = \alpha_1^c\beta_2^c$, $\tau^c = \tau$, and $\alpha_1^c = \alpha_1$. It follows that $\tau = \alpha_1\beta_2^c$, which leads to $\beta_2^c = \tau/\alpha_1$. Thus, all the LCM parameters are identified with the LSEM parameters, and in particular, the controlled effect of M on Y ([3b]), or β_2^c, is identified using the treatment Z as an instrumental variable (IV). Moreover, CDE ([2b]) = PDE ([5b]) $= \beta_1^c = 0$ (where the last equation is by assumption [11]), and TIE ([6b]) $= \tau^c = \tau = \alpha_1\beta_2$.

Assumption [10] requires that each unit effect defined in the section 'Formal Definitions of Causal Effects' remain absolutely the same across all subjects, and thus is called the constant unit effect assumption. This assumption is apparently substantively

unreasonable (even more so than sequential ignorability). Sobel (2008) replaces it with a weaker one:

$$\eta_i(z,m) - \eta_i(z',m') \perp M_i(z), M_i(z') | \mathbf{X}_i, \quad \text{for any } z, m, z', m' \qquad [12]$$

This assumption means that the *difference* between two potential outcomes, $Y_i(z, m) - Y_i(z', m')$, are independent of the *potential* mediators $M_i(z)$ and $M_i(z')$, given covariates $\mathbf{X}_i$. In contrast, [8b] assumes that the *absolute levels* of the potential outcomes are independent of the *observed* mediator, given $\mathbf{X}_i$. For examples in which assumption [12] may hold but ([8b]) may not, see Sobel (2008) and Lindquist and Sobel (2011). By replacing assumption [10] with [12], but still assuming [11] and [8a], one can get the same identification results as in the foregoing paragraph.

Sobel (2008) gives another assumption weaker than [12], under which (alongside [8a] and [11]) the controlled effect of M on Y, β_2^c, is identified in the same way, but the PDE and TIE are not identified. At last, assumption [11] requires $\beta_1^c = 0$, which is also strong. For situations in which $\beta_1^c \neq 0$, see Emsley et al. (2010).

Approach Three: Marginal Structural Models

Ignorability ([8b]) requires that the pretreatment covariates $\mathbf{X}_i$ include all confounders for the M-Y relation. However, there might be some posttreatment M-Y confounders that are not included in $\mathbf{X}_i$ and may or may not be affected by the treatment. This means [8a] holds but [8b] does not. Then replace [8b] with the following assumption,

$$Y_i(z,m) \perp M_i | Z_i, \mathbf{X}_i, \mathbf{W}_i \qquad [13]$$

where $\mathbf{W}_i$ is a vector of posttreatment confounders for the M-Y relationship. If [8a] and [13] hold and some variable(s) in $\mathbf{W}_i$ is affected by the treatment, none of the direct and indirect effects defined in the section 'Formal Definitions of Causal Effects' can be identified using LSEM (and regressions).

VanderWeele (2009) proposes an alternative using marginal structural models (MSM). Consider the group of MSM below:

$$\mathrm{E}\{Y(z,m)\} = \gamma_0^M + \gamma_1^M z + \gamma_2^M m \qquad [14]$$

$$\mathrm{E}\{M(z)|\mathbf{X}\} = \alpha_0^M + \alpha_1^M z + \boldsymbol{\alpha}^{M'}\mathbf{X} \qquad [15a]$$

$$\mathrm{E}\{Y(z,m)|\mathbf{X}\} = \beta_0^M + \beta_1^M z + \beta_2^M m + \boldsymbol{\beta}^{M'}\mathbf{X} \qquad [15b]$$

where the superscript 'M' indicates these are MSM parameters. For eqn [14], γ_1^M is the CDE ([2b]), and γ_2^M is the controlled effect of M on Y ([3b]). Since the LCM ([9a] and [9b]) implies the MSM ([15a] and [15b]), the MSM parameters have causal interpretations similar to their LCM counterparts. Under assumptions [8a] and [13], to identify and estimate the CDE and the controlled effect of M on Y, only eqn [14] is needed. However, to identify and estimate the PDE ([5b]) and TIE ([6b]), one needs eqns [15a] and [15b], and another assumption in addition to [8a] and [13]:

$$Y_i(z,m) \perp M_i(z') | \mathbf{X}_i \qquad [16]$$

which suggests that none of the posttreatment confounders for the M-Y relation in $\mathbf{W}_i$ is affected by the treatment Z_i. If [16] does not hold, PDE and TIE in general cannot be identified. However, if [8a] and [13] hold, the CDE can still be identified and estimated using eqn [14], but LSEM cannot be used, as mentioned above.

Unlike the case of the LCM in the section 'Approach Two: Linear Counterfactual Models with Potential Errors,' where the identification/estimation of the LCM parameters relies on the identification/estimation of the corresponding LSEM parameters, the estimation of the MSM is achieved through a procedure called inverse probability of treatment weighting (IPTW). To remove confounding, both the LSEM and LCM approaches include confounders $\mathbf{X}_i$ into the structural models as covariates. As a result, controlling for confounding and the estimation of parameters are accomplished simultaneously. However, for MSM with IPTW, confounding is dealt with in a separate step (IPTW) preceding the final estimation of model parameters. (Note that although $\mathbf{X}_i$ is included into the MSM ([15a] and [15b]), the purpose of doing so is not to adjust for confounding; see VanderWeele, 2009 for details.)

This two-stage procedure is as follows. First, pseudotreatment and control groups are created by properly weighting the original sample. The weights are calculated using both observed pre- and posttreatment confounders $\mathbf{X}_i$ and $\mathbf{W}_i$ such that, after weighting, the pseudotreatment and control groups become exchangeable (balanced) in terms of $\mathbf{X}_i$ and $\mathbf{W}_i$, while the casual effects in this pseudosample remain the same as in the original one. Thus, all confounding is removed in this stage. In the second stage, regular regression methods are applied to the pseudosample to estimate the MSM parameters. For more details concerning MSM and IPTW, see Robins (1999) and Robins et al. (2000). Using MSM and IPTW entails another assumption that both $\Pr\{Z=1|\mathbf{X}=\mathbf{x}\}$ and $\Pr\{M=1|\mathbf{W}=\mathbf{w}, Z=z, \mathbf{X}=\mathbf{x}\}$ cannot equal to either 1 or 0 for any given $\mathbf{x}_i$, z_i, and $\mathbf{w}_i$. If this is violated, structural nested models (SNM) can be used instead, for which see Robins et al. (1992), Hernán et al. (2005), and Ten Have et al. (2007).

All the aforementioned models (LSEM, LCM, and MSM) assume no treatment-by-mediator interaction on the outcome, but these can be readily extended to include an interaction term; see VanderWeele (2010), VanderWeele and Vansteelandt (2009), and Wang and Sobel (2013). Brumback et al. (2004) provide a general method of sensitivity analysis for MSM.

Approach Four: Principal Stratification

In previous sections, the mediator M_i is treated as some variable that can be (at least conceptually) manipulated. Frangakis and Rubin (2002) propose a different approach, called principal stratification (PS), which focuses on causal effects within subgroups/subpopulations defined by the potential mediators $M_i(z)$ and $M_i(z')$. Since conceptually the potential mediators share the same nature with pretreatment covariates $\mathbf{X}_i$ (except that the former are not observed before treatment and only partially observed after treatment), PS in some sense transforms the issue of mediation into one of moderation. Then,

the questions of interest would be like: What is the effect of Z on Y for those subjects with $\{M_i(z)=m,\ M_i(z')=m'\}$? The subpopulations/subgroups defined as such are called principal strata, and the effects defined within principal strata are called principal effects. A classic treatment of a special case of the PS approach can be found in Angrist et al. (1996). Rubin (2004, 2005) proposes definitions of direct and indirect effects within the PS framework. VanderWeele (2008) discusses the conceptual relations between Rubin's principal direct and indirect effects and the various direct and indirect effects defined in the section 'Formal Definitions of Causal Effects.'

To illustrate the rationale of PS, now return to the recidivism example. For ease of exposition, the mediator M_i – weekly working hours – is transformed into a binary variable (=1 if worked at all, 0 otherwise). In such a case, four principal strata can be defined. The first stratum consists of those ex-convicts with $\{M_i(0)=1,\ M_i(1)=1\}$, who would always work no matter whether they received money transfers or not, and thus may be called 'always workers.' The second stratum includes those with $\{M_i(0)=0,\ M_i(1)=0\}$, who would never work whether received money or not, and are called 'never workers.' The third consists of those with $\{M_i(0)=1,\ M_i(1)=0\}$, who would go to work if they did not receive money transfers but would not go to work if they did receive money transfers, and, following Angrist et al. (1996), are called 'defiers.' The fourth stratum includes those ex-convicts with $\{M_i(0)=0,\ M_i(1)=1\}$, who would not work if they did not receive money but would go to work if they did, and are called 'compliers.' However, as only one of the two potential mediators is observed for each subject, the principal membership cannot be completely identified without further restrictions. Of particular interest is the effect of money transfers Z on rearrest Y for 'never workers', that is,

$$\mathrm{E}\{Y[1,M(1)]-Y[0,M(0)]|M(0)=0,M(1)=0\} \qquad [17]$$

because this principal effect corresponds to the 'clean' direct effect of money transfer on rearrest 'uncontaminated' by the mediator (the potential working status is guaranteed to be 0 no matter whether received money transfers or not), though with reference to only for the subpopulation of 'never workers'.

To identify and estimate the principal effect ([17]), first note that ignorability ([8a]) automatically holds by virtue of randomization. Further, assume there is no complier:

$$M_i(0)\geq M_i(1) \qquad [18]$$

which is called monotonicity. Assumption [18] is in line with the theory that receiving money transfers is a disincentive to work: all those who would not work if they did not receive money transfers would become even more unwilling to work (and thus would still not work) if they did receive money transfers. Unlike Angrist et al. (1996) who make another assumption that the CDE ([2a] and [2b]) is zero – the exclusion restriction, here it is exactly the direct effect that is of interest. Therefore, exclusion restriction does not apply here).

Under assumption [18], one can obtain **Table 1** (observed mediator by observed treatment). Cell 1 of **Table 1** with $\{Z_i=0,\ M_i=0\}$ consists solely of never workers; cell 2 with $\{Z_i=0,\ M_i=1\}$ consists of always workers and defiers; cell 3 with $\{Z_i=1,\ M_i=0\}$ contains never workers and defiers; cell 4 with $\{Z_i=1,\ M_i=1\}$ includes only always workers.

Table 1 Principal strata composition in the recidivism example

	$M_i=0$ *(not worked)*	$M_i=1$ *(worked)*
$Z_i=0$ (no payment)	*Never workers*: $M(0)=0$ & $M(1)=0$ (cell 1)	*Always workers*: $M(0)=1$ & $M(1)=1$ *Defiers*: $M(0)=1$ & $M(1)=0$ (cell 2)
$Z_i=1$ (with payment)	*Never workers*: $M(1)=0$ & $M(0)=0$ *Defiers*: $M(1)=0$ & $M(0)=1$ (cell 3)	*Always workers*: $M(1)=1$ & $M(0)=1$ (cell 4)

Due to randomization, the 'never workers' in the treatment group (cell 1) are exchangeable with the never workers in the control (cell 3), and the former are fully visible. Then, if the never workers in cell 3 can be identified, the principal effect ([17]) is identified. To achieve this goal, one more assumption is needed:

$$Y_i[1,M_i(1)]\perp M_i(0)|\mathbf{X}_i \qquad [19]$$

Jo and Stuart (2009) call this the principal ignorability assumption (they provide a more general form). This assumption means that pretreatment covariates $\mathbf{X}_i$ are all that are needed to predict principal strata membership of the subjects.

If assumptions [8a], [18], and [19] hold, the principal effect ([17]) can be estimated by a three-step procedure which is very similar to propensity-score-based methods. First, use all subjects in cells 1 and 2 to fit a logistic regression in some functional form to predict $\Pr[M(0)=0|\mathbf{X}=\mathbf{x}]$, or equivalently $\Pr[M=0|Z=0,\ \mathbf{X}=\mathbf{x}]$, for each subject in cell 1 (never workers). These predicted probabilities are called principal scores by Hill et al. (2002). Second, use the same fitted regression to predict $\Pr[M(0)=0|\mathbf{X}=\mathbf{x}]$ for each subject in cell 3, which gives his/her principal score. Third, based on these two sets of principal scores for subjects in cells 1 and 3, respectively, one can use either matching or weighting methods to estimate the principal effect ([17]). For details of this estimating procedure, see Hill et al. (2002).

Angrist et al. (1996) show that if ignorability ([8a]), monotonicity $M_i(0)\leq M_i(1)$ (no defiers), and exclusion restriction hold, then the effect of Z on Y for compliers (also called the complier-average causal effect, CACE), $\mathrm{E}\{Y[1,\ M(1)]-Y[0,\ M(0)]|M(0)=0,\ M(1)=1\}$, is identified as the instrumental variable (IV) estimand: $\mathrm{E}\{Y[1,M(1)]-Y[0,M(0)]\}/\mathrm{E}[M(1)-M(0)]$, using treatment assignment as the instrument and assuming the denominator is nonzero.

In some cases, one might be interested in the causal effects within strata defined by a single potential mediator, e.g., $\mathrm{E}\{Y[1,\ M(1)]-Y[0,\ M(0)]|M(1)=0\}$. In the recidivism example, this is the effect of Z on Y for the subgroup consisting of both 'never workers' and 'defiers.' This approach is called single principal stratification; see Joffe et al. (2007) for details. In the context of noncompliance, Mattei et al. (2013) and Mealli and Pacini (2013) use Bayesian analysis to improve the identification of principal effects by utilizing the information of a secondary outcome associated with the primary outcome.

By far, the treatment and mediator are both assumed to be binary. Jin and Rubin (2008, 2009) discuss situations in which the mediator has more categories or is continuous and/or situations where the treatment can take on more values in the context of partial compliance.

A major shortcoming of the PS approach is that the principal strata cannot be observed before treatment. To solve this problem, Hill et al. (2002) propose to define strata with principal scores which are calculated using pretreatment variables. Thus, these principal score strata can be identified before treatment. See Wang and Sobel (2013) for a review of more general forms of principal (score) stratification.

To conclude, all the approaches discussed herein require very strong ignorability types of assumptions that are often implausible in empirical cases. There is no universally superior or inferior approach. The choice of approaches should be made on a case-by-case basis by examining which assumptions are likely to hold (or not) and the nature of the research questions one is asking. Sensitivity analysis is highly recommended. In cases where the type of data available does not permit valid causal mediation analysis, one may want to work on improving the research design, since a good research design is often the most fundamental and effective solution to problems of causal inference. For example, Bertrand and Mullainathan (2003) use résumé experiment to measure more than one potential outcomes for each experimental unit. Thus, no ignorability assumptions are needed. At last, the discussion here focuses mostly on parametric causal models of mediation (except the PS approach). For more nonparametric methods, see, for example, Hong and Nomi (2012) (although their causal model is largely nonparametric, the estimation procedure involves parameterization) and Pearl (2001).

Medical Education

Abstract

This article describes the development and current status of medical education as a professional field of practice and inquiry along two questions: first, how can we educate medical students in such a way that they will become active and permanent learners, ready to adapt to changing content and context of medical practices? Secondly, how can we socialize students into the profession of medicine so that they will become committed to its core principles and occupational values? Two developments are described that significantly contributed to answering these questions, namely problem-based learning and professionalism.

Within a period of less than four decades medical education has become a distinct and highly regarded professionalized field of practice and inquiry. National and international societies have been founded. Thousands of people attend medical education conferences all over the world. New textbooks and journal publications on how to teach and assess in medical education appear on a regular basis. At present, there are at least 20 different peer-reviewed international scientific journals on medical education, not to mention the many opportunities to publish in medical journals. Evidently, the coming into existence of medical education as a distinct and international professional field of expertise has taken place at a fascinating pace.

Not surprisingly, research in medical education overwhelmingly supports the training and preparation of future doctors for medical practice. A recent literature review shows that since the end of the 1980s clinical and communication skills, clinical clerkships, student assessment, and problem-based learning (PBL) were medical education's key themes of investigation (Rotgans, 2011). Publications of the past 25 years strongly focus on the individual student while the psychologist perspective dominates, typically emphasizing the study of individuals. However, medical education as a topic for development and inquiry has a longer history.

Since the appearance of the Flexner report in the United States in the early 1900s, medical education has been in an almost permanent state of change and development (Cooke et al., 2006). Abraham Flexner, a professional educator, was asked to conduct an assessment of all US and Canadian medical schools. His findings shocked the nation. In his report Flexner criticized the mediocre quality and profit motives of many schools and teachers in his country and the inadequacy of curricula and facilities (Flexner, 1910). Only a handful of medical schools (of 155 he visited) were capable of providing an adequate medical education. He therefore advised that, similar to the German system of medical education, all medical schools should become university-based, and that formal analytical reasoning, typical for the natural sciences, should be at the heart of the teaching of physicians.

Following up on the Flexner report the basic medical curriculum has primarily been built around the biological and physical sciences for at least half a century. Minimum standards and requirements for schools were permanently raised, resulting in substantial improvement in the quality of medical education. In light of Flexner's recommendations, schools became university affiliated and began to work toward a better connection between the preclinical and clinical phases. Medical graduates received clinical instruction in academic and affiliated hospitals and were taught by full-time scientists of the preclinical disciplines in modern, scientific, and biomedicine. In many schools this continues to be the standard model for the undergraduate teaching of physicians.

Notwithstanding these changes, curriculum development remained a problem, not only in the United States, but worldwide. By the 1960s, due to the growing complexity of medicine and according to (sub)specializations, everywhere curricula had become rather detailed and ultimately became unmanageable from an educational point of view. Students were required to take courses in too many (sub)disciplines and specialties, some with questionable relevance to their professional role and later career. At the end of the 1960s it seemed as if the most apparent change since the Flexner report was that the typical medical student had moved away from being an apprentice with more clinical experience than he would ever be able to understand, to a physician well trained in the basic sciences though with a rather limited and fragmented clinical experience. From the late 1960s on many efforts in curriculum development were therefore tuned toward bringing this more into balance with the support for content and curriculum development from behavioral and social scientists. These, together with reformist clinicians, ultimately brought new views on how to educate physicians and what to include in the curriculum, in line with individuals' future plans and changing societal demands of what a modern medical doctor should be.

A complete description of the many changes that have taken place in medical education in the last decades could probably fill a bookshelf. But two questions have been leading in these changes, first, how can we educate medical students in such a way that they will become active and permanent learners, ready to adapt to changing content and context of medical practices? Secondly, how can we socialize students into the profession of medicine so that they will become committed to the core principles and occupational values of the

practice of medicine? We describe two developments that significantly contributed to answering these questions, PBL and professionalism.

Problem-Based Learning

Perhaps the greatest milestone for the development of medical education in the past 50 years has been the introduction of PBL. In the late 1960s, PBL, started at McMaster University in Canada, was adopted in 1974 as the basic teaching model by the new medical faculty in Maastricht, the Netherlands, followed soon by the University of Newcastle, Australia, and the University of New Mexico in the United States. From there it was disseminated all over the world to numerous faculties in developed as well as developing countries. The acceptance and success of the new problem-based model was not happenstance. In its infancy, PBL as an educational strategy, and so its later alternates like self-directed learning, integrated learning, task-based learning, focal problems learning, community-based learning, and project-based learning were looked at with suspicion by the medical elite. But soon it proved to foster adult learning, self-responsibility of students, and early introduction of 'real' patient problems to students in a better way than any traditional teaching system up until that time. Instead of medical students having a rather passive role in their undergraduate education by attending and listening to lectures from the knowledge silos of the disciplines, in PBL they had to be active in shaping their own learning process throughout the curriculum. PBL was nothing less than a paradigm shift in students' learning and turned out to become the new trust in medical education. When PBL started to gain a foothold in medical schools it was seen as a paradigm shift and the solution to problems with traditional curricula of students being passive, only memorizing, and failing to learn how to apply and integrate basic knowledge into a clinical context. PBL was at the heart of changing this.

PBL came into existence at a time when there was an urgent need for a new type of doctor. This new doctor would not only be an expert in the somatic aspects of a disease, but also responsible for delivering integrated care, including in his/her diagnosis, treatment, and follow-up procedures, the insights of different knowledge domains including those of the social and behavioral sciences (Van Berkel et al., 2010). PBL was the new strategy toward the modernization of medical education. It appeared to be an appropriate response to the pressures of modernization to make a shift from the pedagogical lecturer-centered approach of education, to a more andragogy, self-directed, innovative adult learning approach (Dent and Harden, 2005; Harden, 2006). What began as an Anglo-Saxon model of teaching and learning soon spread throughout medical schools in Africa, the Pacific, Asia, as well as the Americas. Simply put, using PBL implied you were a modern school.

Notwithstanding its success and efforts of fine-tuning through the years, up to this day it has been quite difficult to establish its superiority in robust designs, nor has it been fully clarified what it exactly is that does the trick in PBL (Dochy et al., 2003; Norman and Schmidt, 1992). PBL studies in medical education still focus on this issue, and also on the question of how to align assessment procedures with the practice of PBL and to bridge the gap between the preclinical and clinical years.

Professionalism and Professional Socialization

The second question – how can we socialize students into the profession of medicine so that they will become committed to the core principles and occupational values of medical practice – is at the heart of medicine's modern-day professionalism movement. Professionalism and processes of socialization into medical school and the medical profession were already at the core of the work of sociologists from the 1950s to the 1970s, based on three landmark studies "The student physician" (Merton et al., 1957), "Boys in White" (Becker et al., 1961), and "Profession of medicine" (Freidson, 1970). Though these first two studies were primarily aimed at testing competing sociological theories (structural functionalism versus symbolic interactionism), they implicitly also signified a major arrival of medicine in its efforts to understand and improve the selection and education of physicians. For example, up to that time medical schools, in particular in the United States, selected students based on 'traits' they must possess to successfully enter and finish their studies. Such traits were also deemed crucial in the development of the currently *in vogue* concept of professionalism, referring to key attitudes and attributes every medical professional should possess (in particular altruism) (Hodges et al., 2011). Research evidenced that the professional education of physicians must also be seen as a continuous, long-term process of growth and development, not only focusing on discrete clinical skills and clinical competencies. Learning the 'rules of the game' and understanding the importance of becoming successfully socialized into the culture of medicine underscored that the attitudes and skills the student develops in medical school and during clerkship training and internships are important sources for his/her later performance as a physician. To this day, however, the question remains whether in the preparation of a physician education at medical school is of more importance than the later work environment. As Freidson (1970: p. 90) noted, a significant amount of behavior is situational and, "(…) people are constantly responding to the organized pressures of the situations they are in at a particular time (…) and what they do is more an outcome of the pressures of the situation they are in than of what they have earlier 'internalized.'" Hafferty et. al. (2014) coined the term 'chameleon socialization' indicating that modern students are not so much socialized into an occupational or organizational milieu but rather into the demands of the moment.

Such insights are vital to the growth and development of every medical student to become a competent, professional expert, and to the necessity of a physician's lifelong learning. Medical schools around the world are increasingly using portfolios as assessment tools, whereby students learn to reflect on their knowledge, skills, and attitudes (van der Vleuten and Dannefer, 2012). In a few schools portfolios have now been introduced as their primary assessment tool. With these portfolios it is the student's responsibility to show and to prove that she or he is to size in a blend of the different required

competencies of a physician – medical expert, professional, communicator, collaborator, manager, scholar, and health advocate (Frank, 2005; Frank and Danoff, 2007).

Today, there is little doubt that medical education comprises a complex program of socialization into the profession of medicine and its culture, and that the study of medical socialization, professionalism, and lifelong learning will continue to be important niches to further develop.

Medical Education as a Professional Field of Inquiry

For not too long the art of clinical practice was transmitted in a guilt-like fashion, driven by the concept of role modeling (Krause, 1996). Nowadays, this practice is carried out more systematically, in teams, according to a plan, grounded in scientific evidence and described, framed, and assessed in line with an index of formalized competencies (Frank, 2005; Frank and Danoff, 2007). Research in medical education contributed substantially to this. The setup of dedicated academic (research) departments of medical education in medical schools all over the world fostered the development of the professional field of medical education. By the time, these departments succeeded more and more in involving physicians and other health professionals and disciplines into medical education research and innovation. For those involved, medical education and the study and advancement of it became an essential part of their livelihood and academic career (Gallagher, 2001; Harden, 2006).

As is known from the sociology of the professions, the optimal cognitive basis for any professional discipline is one whose claimed tasks are sufficiently distinctive to allow the drawing of clear jurisdictional boundaries so that standards of competent performance can be established and controlled (Abott, 1988). Such tasks, however, must not be standardized entirely, because that would make discretionary professional judgment needless (Stevens et al., 2007). This delicate balance applies to the field of medical education as well. In focusing too narrowly on educational theory development, the medical educationalist risks his/her working relationships with the practice of medicine (Albert et al., 2007). However, educationalists may also lose perspective and theoretical grounding when they identify too closely with the medical world (Dimitroff and Davis, 1996). Medical education as a professional field of expertise has been in a continuous effort to keep that balance, occasionally with mixed results. Medical education research has been accused by practitioners of being not conclusive or practical. But where the insights from research are practical and conclusive, the application can nevertheless be limited (Broekkamp and Van Hout-Wolters, 2007). By some, medical education is still seen as an intellectual activity, focusing on how do teachers transmit ideas and/or how do students acquire them. Thus goals of professional performance and behavior would seem to be subordinate to goals of generating new ideas for medical education (Bloom, 1988). This does no justice to current medical education research. Through learning from many different disciplines and perspectives, medical education is now in the middle of an exciting process of theoretical, philosophical, and practical elaboration. While cognitive psychology, with its strong emphasis on the individual learner, dominated medical education research for many years, today the interest has shifted from how do students learn to how do students process knowledge, and toward the study of processes of constructing professional identities conducive to lifelong learning, and learning from and with others in authentic contexts (Mann, 2011). Sociocultural perspectives, which in recent years have become very popular in medical education, emphasize that learning and development is embedded in specific cultural matrices of histories, artifacts, procedures, signs, and symbols (Rogoff and Chavajay, 1995). The cultural matrix not only affects a person's outward behavior but also the internal mental processes generating that behavior. These perspectives, pointing to understanding behavior within sociocultural contexts, challenge our notions of learning, and of the course of individual development. In medical education this means that research is shifting from the individual medical student toward workplace learning and communities of practice, where newcomers become engaged, are transformed, and then, on their turn, transform the community in which they interact (Lave and Wenger, 1991).

Summarizing, at present there is not one theoretical perspective that dominates the field but medical educationalists use different approaches, admittedly still in a rather eclectic way, borrowing from theories and perspectives of sociologists, anthropologists, economists, organizational and management scientists, and so on. While most research in medical education is still effectiveness driven, seeking for solutions to practical problems in order to find what works or what does not, there is a move going on toward more discovery and curiosity-driven research ("why and how does it work") and from quantitative toward more qualitative or mixed methods research approaches (Cook et al., 2008; Rotgans, 2011). Insights and methods from other disciplines contribute to new understandings, for example that education requires continuity and that socialization for professional roles must be seen as closely interdependent with the structure of the situation in which it occurs and for which it prepares. More and more, students are considered active participants in their learning and socialization processes, while teachers are the facilitators to how to learn and what to learn. Fueled by the increasing attention for new and old topics such as team work, lifelong learning, professionalism, medical school culture, management, human development, and academic leadership, medical education awaits exciting times.

Medical Education for the Future: Old Wine in New Bottles?

Now, one hundred years after Flexner's report, are the questions – how can we improve medical education, and produce competent and compassionate physicians effectively and efficiently – sufficiently answered (Cook et al., 2008)? While modern medical education has established the inclusion of the continuous developments in biomedical science, more doubt exists about the preparation of physicians to serve the broader health needs of the society. Notwithstanding the many changes in content and structure of medical education through the years, in the centennial year of the Carnegie Foundation's

groundbreaking Flexner Report that radically changed medical education, the Foundation released with the report *Educating Physicians: A Call for Reform of Medical School and Residence* another call for reform to bring medical education to the next level of excellence (Cooke et al., 2006). Medical schools and residency programs are using modern teaching approaches, like simulations and standardized patients for instruction and assessment. Required competencies and learning objectives are defined, and small group teaching has become quite common. Yet, health care has changed too and new challenges have come to the front, requiring new pedagogies, forms of assessment, and different views on what is expected from the modern doctor. The awareness that, in many places, medical education is inflexible, long, and teacher-oriented is growing. Connections between formal and experiential learning are poor, and there is little opportunity for learners to observe and follow up patients over time. Moreover, students are less well trained in nonclinical roles, nor sufficiently prepared to serve the changing health needs of the society. Only in a limited number of schools across the world clinical and nonclinical experiences, and disciplinary knowledge domains, practical skills, and the teaching and understanding of attitudes and values are well integrated in a healthy blend (Cook et al., 2008).

Old wine in new bottles? – as similar concerns were also raised 50 years ago (Bloom, 1988). Not really. More and more medical educators are becoming aware of the need to prepare learners for the professional roles of tomorrow. Medical education today is more than ever seen as an endeavor contributing to the process of human development and the construction of professional identities. Research in medical education over the past 50 years has significantly contributed to this understanding. Shifts in perspectives have taken place. Medical educators have learned from the views of other disciplines, and are including different perspectives in their ways of dealing with teaching and learning. The insight has gained a foothold that learning takes place through and with others. Learning is now seen as a continuous, participative, and collaborative process that happens within a context, less and less as an individualized acquisition of knowledge and skills.

With this, medical education's role is not finalized, requires reflection and extension, and is becoming less neutral or value free in regard to the content of medical education it helps to produce. With the increasing call on medical educators to prepare doctors for the future the question is legitimate of what responsibility educationalists have in shaping this (Frenk et al., 2010). Similar to the situation 50 years ago, when PBL was expected to play a key role in shaping a new kind of doctor, medical education needs to play a substantive role again in helping to answer the needs of the society, contributing to the human development process of learners and socializing them into a broader concept of the content and culture of medicine (Bloom, 1988). Due to demographic developments, changing disease patterns, increasing health care inequities, health care needs of patients are changing everywhere in a rapid pace. These bring new challenges to the forefront. Graduates are ill equipped to deal with these. For example, while in all societies care at home and in the community needs more attention, in most medical curricula around the world the culture of medicine still means the culture of biomedicine and the hospital. Even now, when in medical education we speak about the importance of workplace learning this covertly means learning in the hospital. Already, for years, a global workforce misbalance exists of an oversupply of hospital specialists at the expense of generalists, primary care physicians, and physicians specialized in elderly care. So is medical education future-proof?

Medical education at the beginning of the twentieth century introduced and substantiated the scientific curriculum. Sixty years later, PBL was at the heart of instructional innovation in assisting to make the shift from memorizing medical knowledge to searching, analyzing, and integrating knowledge. Now another reform is happening, coined as transformative learning (Frenk et al., 2010). Having moved first from formative to informative learning, transformative learning aims, among others, at developing critical, reflective qualities in students in order to be able to synthesize information for decision making and to show leadership for adopting educational models so they can address different local health care priorities (Frenk et al., 2010). By helping to find ways of how to actively engage learners in the community, medical education could play a substantive role again in preparing medical students for the social, economic, and health care realities of tomorrow.

Medical Geography

Jonathan D Mayer and Alex Wagner, University of Washington, Seattle, WA, USA

Published by Elsevier Ltd.

Abstract

Medical geography concerns the relationships between humans and the environment that produce states of health and disease. It also concerns the relationships between health and the spatial structure of society. While medical geography still examines these relationships through understandings of culture, behavior, and techniques emphasizing human–environment interaction, novel concepts and theories are also beginning to be used by medical geographers. These include data from genetics, genomics, and proteomics; Big Data and large spatially referenced datasets; and the exposome, or the sum total of environmental exposure through an individual's life. Medical geography is a subfield not only of geography, but is also of public health. Spatial analysis and data, including GIS, have become essential techniques that are in great demand in academic schools of public health and departments of environmental health and toxicology; they are also techniques that are in great demand in public health agencies that are responsible for disease surveillance and control, health planning, and environmental toxicology. Medical geography is beginning to embrace multiple scales, ranging from the atomic to the macro-social and global scales.

Introduction

There are two ways of understanding medical geography. The first includes only research done by groups formally identified with departments of geography. The second is far more inclusive and includes all research that uses spatial methods and theories to understand health and disease. The latter has been recently reviewed (Mayer, 2009).

This presents a definitional dilemma. Medical geography is a subfield of geography and of public health – and indeed, of population-based medical research. One of the most important trends in medical geography is the increasing sophistication of medical geographers in epidemiology (including molecular epidemiology and genetic epidemiology), environmental health, exposure modeling, and biostatistics. Conversely, spatial concepts and methods – particularly GIS and spatial modeling – have become increasingly important in all of the more traditional fields of public health. Thus there is much ambiguity surrounding the term 'medical geography.' Many who were trained formally in medical geography have moved wholly or partly into other disciplines such as epidemiology, while others trained in a variety of fields including epidemiology and clinical medicine have moved into departments of geography. Restricting 'medical geography' to work that is done only by people with primary academic affiliations in departments of geography is unduly narrow, and misses the majority of research in what, intellectually, is clearly medical geography.

Recent developments in medical geography include the integration of political ecology with health, the nascent use of genetic and molecular methods, increasing use of more sophisticated GIScience and 'Big Data' spatial analysis of health and disease, and the use of social theory in understanding health. Equally important is the adoption of spatial methods to fields other than institutional geography. Major contemporary global and local problems, ranging from globalization and global health inequities to environmental change, have been highlighted. In the past two decades especially, noninfectious diseases such as cancers, heart diseases, and neurologic diseases have become as important to medical geography as are infectious diseases and their relations with the environment and culture.

The 1990s was a decade of change. Some argued that medical geography overemphasized the 'biomedical model' of disease. This critique was particularly strong in places where spatial methods were no longer regarded as 'cutting edge' or were considered obsolete, and where social theory was dominant; Australia–New Zealand and Britain were the prime movers in this development of what has come to be labeled 'health geography' though the critique of the biomedical model has been notable in the US as well. Ambiguity remains, though, since (1) the so-called biomedical model is protean and ill-defined and (2) multiple terms are used to denote medical geography, including the 'geography of health and disease,' 'epidemiologic geography,' 'public health geography,' and 'spatial epidemiology' (Mayer, 2009). Defining mainstream medical geography as being primarily limited to social theoretic approaches has had three main consequences: (1) much of value was learned and continues to be learned by including social theory; (2) many scientific medical geographers have switched the focus of their publications away from geographical journals to those in epidemiology and medicine; and (3) the majority of researchers who use spatial methods and concepts are not 'formal' geographers, most of whom are unaware of the internal geographic debates of the 1990s, and, if aware, consider them to be esoteric and lacking relevance for their research.

The Evolution of Medical Geography

The ecological approach to medical geography was dominant following World War II until spatial analytic techniques were introduced into medical geography in the 1960s, as the quantitative revolution spurred the growth and expansion of medical geography. Medical geography also embraced the developing approaches of health services research and the

delivery of care. Critical questions such as barriers to access, including geographic barriers to access, were brought into focus by the Great Society Programs and by ethical arguments surrounding the right to health care. This focus is broadly labeled as the geography of health care and is beyond the scope of this article.

The ecological imagination considers disease as the result of maladaptive relations between people, their behavior, and the environment (Meade, 1977). Much of this work has been based on the intellectual tradition that began with Jacques May (1958), a surgeon-turned medical geographer affiliated with the American Geographical Society. May wrote extensively about the ecology of disease and the geography of nutrition. His interest stemmed from his experiences and observations on the relations between culture, habitat, and disease in what was then called 'French Indochina.' Disease ecology considers the complex relations between the physical, sociocultural, and biological environments on the one hand, and the resulting patterns of disease on the other. May suggested that disease only occurs when there is coincidence in time and space of agent (pathogen) and host. The emphasis was almost entirely on infectious disease caused by pathogens such as viruses, bacteria, and protozoa, on the virulence of these agents, and on the susceptibility of hosts, those organisms that harbor the disease. Most medical geography has been concerned with human hosts, though clearly diseases among nonhuman organisms can also be analyzed geographically.

The 'One Health Movement' and EcoHealth, both of which have become major interdisciplinary movements in fields ranging from ecology to public health, hold that the division between human and animal diseases, and, indeed, between these and ecosystem health, is artificial and impedes both understanding and the attainment of sustainability in societies and nested ecosystems. Many of the roots of this view are found in ecological medical geography, in which diseases with animal reservoirs, such as African trypanosomiasis ('African sleeping sickness') or yellow fever were considered, both of which have animal reservoirs. The other roots include sustainability science and biological ecology. The One Health movement will undoubtedly be further incorporated into medical geography in the next few years (post-2014).

Most medical geographers, like epidemiologists, identify Hippocrates as their intellectual precursor. In addition to being a prominent Greek physician, he was also a major thinker in the relationships between the physical environment and health. In his essay, *Of Airs, Waters, and Places* (Dubos, 1965), Hippocrates noted the importance of climate, water, and other physical characteristics as influences on the health conditions of areas. Some of his environmental thinking has stood the test of time. Diseases as diverse as malaria, dengue, schistosomiasis, and arsenicosis have their roots in the natural environment and in human interaction with the environment.

Few advances were apparent in medical geography until the latter part of the eighteenth century and the nineteenth century, with the advent of the 'public health movement' in Europe and the Americas. This was not a monolithic movement, but importantly many thinkers and social activists saw the local environment as a determinant of public health. Much of the attention was naively devoted to cleanliness and the minimization of filth. The 'miasma theory of disease' held that foul areas and polluted conditions caused all diseases. Rodent control, water quality, and air quality were all major issues in the public health movement.

Some of this thinking was based on observation, and many diseases are associated with an abundance of rodents, poor water quality, and air pollution. Dr John Snow, a London anesthesiologist, is usually considered to be the major progenitor of epidemiology, medical geography, and environmental health. GIScience and cartography courses frequently begin with descriptions of Snow's conviction that the cholera epidemics in mid-nineteenth century London were caused by contaminated water, though he had no way of knowing that there was a microbial basis to the disease. A pleasing legend is that he mapped cholera cases, and noted that a water pump was at the center of the distribution. According to this narrative, Snow convinced local officials to remove the handle of the pump, and the epidemic ended, all because of his disease map. The truth is a bit different, though the simple narrative is still erroneously taught in epidemiology and subfields of geography. By the time the pump handle was removed, the epidemic was waning, a development that preceded Snow's map. He conducted an epidemiologic survey of the affected and unaffected population – effectively, a case-control study. He discovered that a disproportionate number of cases received their water from one private company, and that controls obtained water from another. This elevated risk led to the removal of the pump handle, which was associated with only one of the water suppliers. Snow subsequently mapped the distribution of cases, and the famous Broad Street pump was near the center of the distribution. He incorporated elements of what later became epidemiology and medical geography as one part of his analysis and civic activism (Paneth, 2004).

Ironically, and simultaneously with the increase in environmental understandings of disease was the fundamentally important discovery of the microbial basis of infectious disease. This discovery completely reoriented biological science to an entirely different scale, and away from the environment. The 'germ theory of disease' and the related doctrine of specific etiology exerted a profound and lasting influence on science and medicine that countered the major emphasis of geographic studies on the macro level. Pasteur and Koch discovered the microbial basis of infectious disease between approximately 1860 and 1885. Koch won the Nobel Prize in Physiology and Medicine in 1905 for his discoveries. It was not until the second half of the twentieth century, with the development and emphasis on the field of environmental health in public health, that there was recognition that both the micro and the macro scales are important.

The practical utility of disease mapping and medical geography was further realized during World Wars I and II, where again it became important to know what diseases would be encountered by troops who went abroad from their homelands. This knowledge was of obvious strategic utility; interestingly, it has received minimal consideration in histories of medical geography. Disease mapping thus played a role in both wars, as well as in the Vietnam War and the wars in Iraq and Afghanistan. It has practical utility in advising travelers about vaccination and in forming differential diagnoses in clinical medicine should somebody return from travel with symptoms that could lead to broad differential diagnoses (Mayer, 1989).

Following World War II, the major emphasis on medical geography was initially on the development of disease ecology, first based largely on the work of May and subsequently on that of Learmonth (1988) and others who also sought to understand the interplay of biological, cultural, and environmental factors in disease. The mobility of populations became another theme for investigation. Prothero (1965), for example, investigated the role of migration in malaria transmission. This research was influential in the formation of policy with the World Health Organization (WHO).

The 'quantitative revolution' in geography of the 1950s and 1960s provided an impetus to new techniques of studying disease and health care. Some of the earliest research using more sophisticated quantitative techniques was by researchers such as Gerald Pyle (1971) who investigated the spatial patterns of cancers, heart diseases, and strokes in Chicago. This research was also significant in that it represented some of the earliest research by geographers to relate the spatial patterns of diseases at a metropolitan level to urban structure and to emphasize the geographical patterns of noninfectious diseases.

Spread of Disease

Some of the earliest work in medical geography following the beginning of the quantitative revolution considered the mechanisms by which disease spreads from place to place. Though this is called 'diffusion' in geography because of Hagerstrand's research on the spatial diffusion of innovation, the term 'diffusion' is a misnomer. In the context of disease, 'diffusion' is not recognized. The simpler 'disease spread' is both correctly evocative and universally recognized. Early geographic work on disease spread includes Pyle's study of the spread of cholera in the USA in the nineteenth century (Pyle, 1969), which demonstrated that the spread of cholera reflected the change in regional structure and connectivity. As transportation systems developed and places became better connected from the early to the late nineteenth century, the pattern of spread of cholera changed from a distance-based 'contagious' diffusion pattern to one based more on the settlement hierarchy and therefore usually termed a 'hierarchical' pattern by geographers – another term that breeds misunderstanding in an interdisciplinary context. Since then, disease spread has become such an important theme in medical geography and public health that it is impossible to summarize the research here. In general, the research has become less descriptive and more predictive. It is difficult to discover an infectious disease whose spread has not been analyzed.

GIScience and the Spatial Analysis of Infectious Disease

Pyle's research on cholera was followed by the groundbreaking statistical and mathematical research by Haggett, Cliff, and colleagues on the spatial distribution of measles (Haggett, 2000). Subsequently, these early works led to more sophisticated analysis and modeling of the spatial variation of disease, facilitated by the development of GIS. Well-known to geographers and now considered to be an essential tool in public health, GIS allows the interactive display of many layers of spatial data, so that, for example, knowing the environmental requirements for the survival and propagation of a vector can lead to a precise display of areas where that vector might survive.

Infectious disease models have become more sophisticated in their ability to predict the incidence and prevalence of disease using a GIS model by exploiting such spatial statistical techniques as inverse distance weighting and kriging. These techniques are also valuable for interpolating population data, which is required in larger volumes as disease mapping is better able to represent the heterogeneous data involved in disease mapping (Tatem et al., 2012).

Predictive spatial and epidemiologic modeling has the potential to assign probabilities to where and when epidemics may arise. During an ongoing epidemic, the ultimate test will be to predict with accuracy which places are most vulnerable to disease spread. Such prediction can be essential in deciding where to focus health education campaigns, vaccination, and even quarantine. Advances are being made in this direction (e.g., Matrajt et al., 2013; Chao et al., 2011; Matrajt and Longini, 2010). During the World Trade Organization meeting in Seattle in 1999, real-time symptomatic data, called 'syndromic surveillance,' was made possible for local emergency departments. Subsequently, GIS has been incorporated into such systems on a limited basis, with the goal of improved public health surveillance that incorporates real-time display of spatial data. In some areas, it is possible to query the system for a symptom such as 'vomiting.' A real-time display of emergency department visits with patients who have vomited will result, with the ability to display spatial, temporal, and other epidemiologic patterns. Such developments should provide an early warning that an epidemic is occurring or that a bioterrorist event is in progress. Though it presents ethical dilemmas, effective disease surveillance and control is being facilitated by the ability to trace movement patterns based upon GPS embedded in mobile telephones; novel applications of this technology have been used in Africa and elsewhere as important inputs to tracking a particular epidemic.

Chronic Disease and the Environment

Chronic diseases have a long onset and remain present for a long time or relapse and remit over long periods. Causation is usually multifactorial. Unlike infectious diseases, it is not possible to point to one factor that gives rise to a chronic disease. The Global South faces a 'dual burden' of chronic and infectious diseases. While people may be at high risk for cholera or malaria, they are also at risk for cardiovascular disease and cancer as a result of environmental exposure, changing patterns of nutrition, and decreasing exercise.

Chronic diseases are influenced by both genetics and environment. 'Environment' is typically defined as that which is external to the body. Thus, in most writing in the health sciences 'environment' does not necessarily correspond with earth science and social science notions of environment. The oft-repeated statement that 90% of all cancers have an environmental component is easy to misinterpret. It does not mean that the source of 90% of all cancers has an ecosystem cause. In

epidemiology and environmental health, 'environment' may be used in both senses.

There is a strong need for standard nomenclature that includes the health sciences, the social sciences, and environmental studies. The dichotomy between chronic diseases and infectious diseases is turning out to be false, yet use of the terms as distinct persists in medical geography and elsewhere. In the Global North, where there is adequate access to antiretroviral therapy, HIV/AIDS can usually be effectively treated. AIDS has turned into a chronic infectious disease. Moreover, many of the chronic diseases have turned out to have infectious causes. Classic examples are HPV (human papillomavirus), which causes 90% of cervical cancer cases, and the bacterium *H. pylori*, which causes 90% of peptic ulcers. A more appropriate set of descriptive labels is 'infectious diseases' and 'apparently noninfectious diseases.'

Within medical geography, interest in chronic disease is centered on two foci: (1) understanding the environmental exposure pathways of a particular disease and (2) understanding the roles of social system attributes in introducing or perpetuating these exposure pathways. With respect to the former, medical geographers may work with advanced statistical techniques to better understand the variance in prevalence and incidence rates for a disease in a particular place. Alternatively, similar results may be obtained through epidemiology-based research designs that can help establish exposure pathways of interest with regard to a particular disease. These study designs include case-control, cohort/prospective cohort, and other standard designs.

'Big Data' has the potential to advance understandings of infectious and noninfectious diseases. Again, exposure pathways are key. We are approaching a time when actual exposure to environmental contaminants is possible, so that as an individual goes about for a day, exposure to noxious environments may be measured and patterns may then be analyzed using large spatial datasets. Big Data refers to databases with large volumes of different kinds of data. Research within the relational structures in these databases has the potential to resolve connections between disease and environmental, social, and genetic drivers. Subsequently, these connections will direct future research toward areas of higher potential impact on disease outcome. For example, a recent study in Kentucky between local pharmacies and patients has combined asthma patient data with spatial data. Subjects can use asthma inhalers that are attached to small sensors that transmit the location where each inhalation of medication is taken. In turn, such a novel application allowed the integration of patient location and environmental conditions, including meteorologic conditions (MacDonald, 2012).

Much of this analysis would not be possible without advances in the data storage and modeling capacity of GIS. For example, spatial data obtained through mobile devices can be brought into a GIS and analyzed against neighborhood attributes, demographic data, meteorological conditions, etc. The ability to analyze individual movements, as opposed to fixed locations such as individual addresses, has contributed to expanded definitions of 'neighborhood' and 'community,' which are important units of analysis in medical geography.

Taking advantage of the evolving character of medical data promises new advances in computing the geographic context of both infectious and chronic diseases. However, working with Big Data in medical geography will require advanced database management structures within geography, particularly GIScience. This developing framework parallels foundational work in environmental hazard and sustainability research, two areas where human health is becoming increasingly more apparent as an important domain for planning and impact analysis. The emphasis on electronic health records also has the potential to yield tremendous information in a context such as an urban slum in Ghana, where local health-care workers may not only record health information into a handheld unit that communicates with a server, but also where the data are geotagged. Such an application has the potential to improve vaccination rates and to contribute to preventive medicine through targeted health checks.

One key element in understanding individual risk of exposure to ozone and other environmental contaminants is information on a person's daily movement. GPS tracking in mobile devices, multilayer map displays, and a refined understanding of how an individual's surrounding shapes exposure are all advancements within geography that are expanding understanding of the health impacts of exposure to environmental contaminants.

New concepts like the exposome, defined as the measure of all the exposures of an individual over a lifetime and how those exposures relate to health, are aiding in these efforts. Not only is this concept helpful in predicting individual health impacts it also offers a useful metric for defining the health resiliency of a community. Environmental contaminants, which result from both natural and technological causes, are a growing field of interest within medical geography, an interest that parallels advances in the fields of epidemiology, toxicology, and public health. Such contaminants are transmitted through air, water, or soil, and can initiate, or exacerbate, existing cases of chronic disease.

Ozone, for example, is an airborne chemical formed *in situ* through primary precursors that may be a combination of naturally occurring elements and human-caused pollution. Asthma and COPD (chronic obstructive pulmonary disease) are particularly affected by pollutants since airborne contaminants cause inflammation in the respiratory system. Because of systemic inflammation, particulate and gaseous pollutions have been causally related to the development of atherosclerosis and myocardial infarctions ('heart attacks') and to serious arrhythmias that could be immediately life-threatening. These relationships have been demonstrated for people who are stuck in traffic in polluted conditions.

Social Environment

Medical geographers are also interested in the aspects of a social system that introduce or perpetuate an exposure pathway. Social epidemiologists demonstrated that neighborhood and local areas can themselves be either protective or pathogenic – and insight enabled by using multilevel or hierarchical models, in which outcome is a function of individual as well as areal-level data. This methodological development has been one of the major innovations in understanding since 1990. Theoretically, this understanding

is grounded in sociological, demographic, and urban geographic thoughts.

The insights that spatial analysis has provided in understanding patterns of cancers and cardiorespiratory diseases have been reviewed recently (Mayer, 2009). For diseases of uncertain cause, spatial analysis can be instrumental in identifying causes that covary spatially at the same scale as the disease. Such techniques have facilitated insights into the causes of asthma and other respiratory diseases, environmental etiologies of ischemic heart disease and stroke, and environmental contributors to neurologic disease such as multiple sclerosis (MS). All involve both genetic and environmental factors. Usually, small variations in the host genome are 'turned on' by environmental switches. Gene expression is thus partially determined by the environment, so that a gene that might predispose to MS becomes expressed only with the appropriate environmental exposure. This process is termed 'epigenetics' and is only now beginning to be incorporated into work done by medical geographers.

Political Ecology of Disease

Political ecology – the marriage of cultural ecology and political economy – has had a great impact in understanding the relationships between globalization, power, environmental modification, and their effects on individuals and groups. The advantages of applying political ecology to health and disease were first suggested in 1996 (Mayer, 1996). Disease ecology considers the interaction between environment, population, and behavior (Meade and Emch, 2010). However, disease ecology has not traditionally considered the roles of political and economic power at varying scales. In adding these themes to traditional disease ecology, one arrives at a political ecologic understanding of health, which fundamentally unites social explanations with environmental and behavioral explanations of disease. For example, the 1960s saw the completion of 'Big Dams' as parts of environmental control and economic development projects; two prominent examples are the Aswan High Dam in Egypt and the Akosombo ('Volta River') Dam in Ghana. In many ways, the completion of these dams was beneficial for all concerned, but the formation of large, upriver lakes have had major, unintended health consequences. Because of changing ecologies and greater human exposure to the lake, e.g., Lake Akosombo, for washing, bathing, recreation, fishing, and other economic activities, the prevalence of three major diseases increased upriver, and, to some extent, downriver. These are malaria, onchocerciasis, and schistosomiasis, which are all vector-borne infectious diseases. All are major burdens to health in Ghana generally, causing significant mortality and morbidity.

In one sense, the increases in morbidity and mortality due to the completion of the Akosombo Dam have been caused not only by environmental factors, or even human–environment interaction, but also by strong government influence and economic 'imperative' within the context of the global economy. The dam was constructed to support the well-being of one industry, bauxite, and to some extent, one corporation within that industry. It was strongly pushed by the government of Ghana, both to increase national wealth and to improve quality of life and human well-being. Without electrical power, it would be difficult for either of these to happen.

Conclusion

Medical geography and health geography are intertwined, and there is little advantage to attempting to differentiate between the two. The incorporation of social theory in the 1990s and of models other than the biomedical model in attempting to understand and explain both health and disease added new dimensions. At the same time, further development of biosocial medical geography has yielded insights into disease causation and the pathways of exposure to environments that have the potential to cause disease in populations. Moreover, genomics and molecular methods are beginning to affect medical geography, allowing the researcher to understand specific genetic structures of a pathogen, or of a host, and to understand the environmental 'switches' that result in the expression of genes. Both infectious and apparently noninfectious diseases result from the interaction of genetic and environmental factors. Exposure to environments that generate disease is caused by individual behavior, culture, belief systems, social structure, and many other factors. Geography emphasizes scale, and one of the potential contributions of medical geography is that it provides us with concepts and tools that facilitate integration of knowledge at scales ranging from the molecular to the macro and even global scales. Contemporary developments in spatial data and data structures, as well as genomics and proteomics, may well herald a new age that will yield novel explanations for disease causation. Traditional medical geography, when merged with these emerging theories, techniques, and methodologies, together can result in entirely novel explanations for why population health patterns have their own particular signatures. Ultimately, these developments have the potential to further human health and well-being.

Medical Profession

Abstract

Medicine is a profession. Professions are assumed to be altruistic, self-governing in the public interest and having work autonomy. Medicine rose to a height of power in the middle of the twentieth century when it dominated health care, health policy, and societal definitions of health and illness. This medical dominance has been increasingly challenged by payers, other health occupations, medical industries, and patients. Explanations for a decline in medical power range from pluralistic interest group explanations, through theories of elite power, to arguments that medical power is always dependent on its congruence with the interests of powerful capitalist classes.

Social scientists analyze medicine as an occupation rather than writing biographies of great medical figures or histories of medical discoveries. Emphasis is on the ways in which the production and application of knowledge in helping prevent, cure, or care for illness is an organized social activity.

The term profession implies differences from other kinds of work such as job, position, trade or craft. As individuals, our work is partly determined by our family's social position and, in turn, strongly influences our own income, social status, and class location. As an occupation, medicine reflects the social structures of which it is a part and in turn influences these structures.

Professionals are assumed to be experts in an applied field and are generally of high income, prestige, and social position. Today the ever-increasing number of occupations claiming expertise all try to assume the title of 'profession' and its accompanying privileges. Medicine is often referred to as the archetype profession because it exemplifies the professional ideals of expertise, an altruistic rather than self-interest orientation, high work autonomy, and occupational self-government.

This article focuses mainly on medicine in the English-speaking countries. Yet, even among these nations, differing social structures and varying social science traditions produce somewhat contrasting visions of medicine's historical trajectory. In particular, the United States is an outlier in having less direct state and more direct corporate involvement in medicine. In most other nations, the state has had a much more influential role (Johnson et al., 1995).

Medicine as a Profession

The traditional professions have a history rooted in the craft guilds of the Middle Ages (Krause, 1996). By the nineteenth century, the professions promised a mode of work which was more autonomous, complex, and less alienating than the deadening factory systems of the industrial revolution. Freidson (2001) has pointed out that bureaucracy, business, and professions are contrasting work principles, bureaucracy characterized by hierarchy and routine, business by material gain within markets, and the professions by claimed expertise, self-government, and an altruistic orientation to their service. These characterizations are overdrawn but do provide a flavor of the ideals, if not the reality, of such types of work.

From the 1930s to 1960s, the social sciences largely accepted the professions' own view of themselves as ethical and self-governing in the public interest. Actual studies of medicine, however, indicated that the profession was not as rigorously self-regulating or altruistic as its practitioners claimed (Coburn, 1999; Freidson, 1970; Larkin, 1983; Larson, 1977; Light, 2010; Starr, 1982; Willis, 1989). By the latter part of the twentieth century, the medical profession was viewed as exploiting its monopoly powers in order to reduce competition, to secure higher incomes, to control or exclude competing occupations, and to protect, rather than correct, its own miscreants. The core of professional identity came to be defined as autonomous work and professionalization as a collective strategy for attaining and maintaining control over a set of tasks (Larson, 1977).

Sociologists began to focus on the power of medicine to orient medical care as much to its own interests as to the health needs of patients or populations, hence the term 'medical dominance' (Freidson, 1970). Dominance refers to the ability of medicine to control its own work, the activities of other health occupations, the way medical tasks are socially organized and delivered and even the very definitions of what constitutes health and human well-being. The term dominance, however, may be interpreted in strong (medicine is hegemonic) or weak (medicine is an intermediary power) versions leading to contrasting explanations for medical power. There was an increasing skepticism about professional altruism (Saks, 1995) which some, however, feel was overdrawn (Strong, 1979).

Medicine, a Heterogenous Profession in a Complex Service Industry

To speak of 'the medical profession' in contemporary times is to ignore the profession's internal and international variation. Within nations there are dozens of medical boards, associations, regulatory agencies, and specialty groupings. Public health, academic, and curative medicine have divergent aims and somewhat competing philosophies. Physicians work in a variety of organizations and settings which differentially shape their

work and policy orientations. Moreover, medicine is now practiced within highly complex divisions of labor in which the image of the doctor with the little black bag plays a part only as romantic history. Rather, there is a 'medical industrial' complex consisting of the pharmaceutical industries, hospital 'factories,' medical supply and equipment industries, and hundreds of nonphysician occupations and professions, from massage therapy through computerized medical imaging. The drug industries are powerful and increasingly expensive drivers of the health field, its research directions and applications. In a number of the developing societies, in addition to western-type medical personnel, there persist a variety of indigenous healers. This curative complex is attached to various kinds of private and public payment systems. In the world's richest 38 nations of the Organization for Economic Cooperation and Development (OECD), total expenditures on health average 9.5% of Gross Domestic Product (Australia 9.1; Canada 11.4; United Kingdom 9.6), with the United States being the high outlier at 17.6% yet having relatively poor average population health (OECD Health Data, 2012). In nations with government provided or subsidized care, health, along with education, consumes the largest proportion of government budgets hence the relationships between medicine and the state are critical.

In addition to formal curative care, there is a vast social complex consisting of health-related areas from nonorthodox or alternative healing to the diet, wellness, mental/emotional well-being, and fitness industries. Well-being, bodily appearance, and longevity are at the center of concern within all of the advanced nations. Modern societies are said to be 'medicalized' although the medical profession is only one of the many sources of this medicalization with the drug industries a major source. We are living in a 'risk society.' Almost any activity now carries with it an assessment of its possible threat to health. Moreover, in a secular and materialist society, human life is not viewed as preparation for an afterlife but as an end in itself. There is a desperate desire to delay death, avoid or control risks, and to appear and be, young and vigorous, or at least not old and decrepit. In all of these areas, medicine and its surrounding services have something to say. However, while we can speak of medicine, the state or other institutions none of these actors are unitary or impermeable. All of them are heterogenous and perfused with influence from 'the outside' by other actors in complex networks. For example, medicine and the state have symbiotic interrelationships and influence one another's internal functioning.

Medicine is always part of, rather than 'above' society. In the nineteenth and early twentieth centuries, medicine was overtly sexist reflecting the patriarchal social structures of the time. At various times, women, Jews, and blacks were prevented from entering medicine. In the nineteenth and early twentieth centuries, women patients were viewed as fragile victims of their own uteruses (Ehrenreich and English, 1972). Before and during World War II, the profession in Germany actively displayed antisemitism and physicians took part in the Holocaust. At all times in the modern world, the poor tend to be less well-represented in medical ranks than are the rich or middle classes. Under state command economies, medicine sometimes, as in psychiatry, directly served the purposes of the state in oppressing or subduing citizens. In Europe and North America, medicine early on was eugenicist and in accord with the norms of the time some physicians sterilized the mentally ill and those with low cognitive functioning. Later, tranquillizers often used by doctors to treat depression in women also served, it is claimed, to 'adjust' women to what many perceived as oppressive social roles. In numerous societies, while there have been many insightful and progressive individual medical practitioners, the organizations representing physicians have most frequently had conservative political views and have generally opposed such welfare state measures as state health care or universal health insurance measures. Given the tendency to reflect the interests, values, and regulatory regimes of the era in which it is embedded Foucaultians see medicine as part of the movement to control and regulate populations (Petersen and Bunton, 1997; Turner, 1995).

Internationally, medicine ranges from doctors using basic medical equipment to highly skilled experts employing complex computer assisted procedures. It encompasses practitioners who routinely accept bribes to high status doctors catering to rich clients. While some countries or regions have a physician oversupply others are underserviced. Internationally, 47% of the member nations of the World Health Organization (WHO) have less than one physician per 1000, many nations in Southern Africa have less than one per 10 000 population. At the other end of the spectrum, a number of nations have more than 40 per 10 000 physicians, including, for example, Austria, Cuba, Georgia, Kazakhstan, and the Russian Federation. The United States has 24, the United Kingdom 27, Australia 30, and Canada 20 physicians per 10 000 population. Despite the persistence of indigenous healing systems, globalization has been accompanied by an almost universal reverence for highly technical medicine to which elites around the world want access. Such a reverence for high-tech curative care constitutes a problem for poor nations.

Historical Development

In the second half of the nineteenth century, medicine was internally fragmented and fractious, with various competing healing modalities ranging from allopathy to homeopathy to eclectics. Medicine was composed almost entirely of males and faced with a variety of 'external' competitors from bone-setters to midwives within pluralistic healing systems. Many lay persons thought they knew as much about health and illness as did physicians. While anesthetics and aseptic techniques had helped to improve surgical procedures, medical therapies generally were not far removed from the bleeding, blistering, and purging prevalent earlier.

By the middle of the twentieth century, in less than 100 years, medicine had risen from its previously lowly position to one of social and cultural authority (Starr, 1982). Physicians controlled key health care institutions and were the acknowledged experts in what constituted disease and what should be done about it. Medicine first unified and then established its dominant position in health care (Larson, 1977). In mid-century, unlike in earlier times patients generally benefitted rather than suffered from visiting a doctor. Medical education was lengthy, rigorous, and science- and technology-based. Entrance into medical school was highly prized, competitive, and exclusive. Physicians had high status, unprecedented autonomy and authority, and high incomes.

Medicine heavily influenced definitions of health and illness and largely controlled both other health occupations and health policy.

The major trend for medicine has thus been that of an increasingly scientifically sophisticated, powerful, and efficacious profession. There are, however, dissenting views about the positive effects of orthodox medicine and its emphasis on curative therapies. Medicine has possible iatrogenic effects on the individual, the institutional, and the social level (Illich, 1975). Powerful technologies and drugs often have negative side effects, which threaten to overwhelm their positive influence. For example, the proliferating use of antibiotics creates drug-resistant organisms. Medicine still is more effective at treating injuries, trauma, and acute disease than it is at curing the rising tide of more chronic diseases in aging populations. A biologically based curative medicine individualizes the social causes of illness, hence leading to a de-emphasis on the social determinants of health and on preventive medicine and health maintenance. Professional power may rob the public of the inclination to view themselves as responsible or competent regarding their own health.

Regarding the aim of medicine, improved health, and well-being, social analysis indicates that more doctors and more of health care are not necessarily the major factors leading to the improved health of populations (Evans et al., 1994; McKeown, 1979; Szreter, 2002). Most recently, WHO has published a report on the Commission on the Social Determinants of Health Final Report (2008) which contends the ways people are brought up as children, the way they live and work, rather than health care, are the important determinants of population health. The WHO Report directly implicates unfair economic arrangements and 'bad politics' in producing health inequalities within or between nations. Within these new paradigms medicine and health care, focused largely on individual cure, are less intellectually salient than they once were although they are certainly not less socially or politically central.

Medical Dominance: Medicine, Central and Powerful yet Challenged

The chief focus of social scientists in the past few decades has been on the power of the medical profession to ensure that health care policy and procedures suit their own interests, that is, medical dominance. This area of interest, introduced most prominently by Freidson, was later directly or indirectly tackled in various nations (Coburn, 1999, 2006; Hafferty and McKinlay, 1993; Larkin, 1983; Light, 2010; Starr, 1982; Tousijn, 2002; Willis, 1989, 2006). However, the questions arose – if medicine was dominant within health care, if it indeed controlled its own work, other health occupations, health policy and the way societies viewed health, has medicine always been dominant and does medical dominance vary in different national contexts? With the advent, before and after World War II, of the rise of welfare states, national health systems and subsequent focuses on health care costs, a major trend of challenges to medical dominance and a possible sequence of 'the rise and fall' of medical power ensued (see special editions of Health and Social Behavior, 2010; Health Sociology Review, 2006; Health Politics, Policy and Law, 2004).

It is accepted that medicine was uniquely powerful in the mid-twentieth century and that there have been challenges to that power ever since although there are still disagreements about whether or not medicine was 'ultimately' dominant. Challenges have arisen from other health occupations struggling against medical control or scopes of practice, that is, 'turf wars,' by corporate and state payers regarding the costs of medical services, by patients over problems with medical self-regulation and discipline, by hospital complexes, and by industries, such as the pharmaceutical industry, which attempt to shape health care to their own interests. It is now felt that medicine, while still powerful, is somewhat less so than it was, although the degree of decline is more obvious regarding health policy than in some other areas. As Tousijn (2002) points out, declines in power may vary by the dimension of dominance one is examining. In what follows the historical rise of, and contemporary challenges to medicine are traced through a brief analysis of medical knowledge and practice. We then note varying explanations of such historical trajectories.

Medical Knowledge

Doctors in the eighteenth and nineteenth centuries claimed authority, not on the basis of medical discoveries, but because of their gentlemanly status. This authority was underwritten by attendance at elite universities and knowledge of classical learning. Medicine was a male middle-class enterprise. Women, minority religious or racial work groups, and the working class were largely excluded.

In the nineteenth and early twentieth centuries, medicine increasingly asserted authority because it claimed association with the rapidly rising prestige of science. But, this was a particular kind of medicine; a medicine based on individual biology and the germ theory gained ascendance over the public health medicine and various health-related political movements rather focused on the social roots of illness in poverty and poor living conditions.

Foucault emphasized the inseparability of knowledge and power. Control over the production of knowledge as well as credentialism are certainly two of the strategies used by medicine to gain and then maintain control over health care. The profession administers the production of knowledge in medical schools and health science complexes and gains control over it even though much of this research is carried out by basic scientists rather than physicians. Physicians have a monopoly over direct access to patients and to prescription drugs, crucial aspects of the research endeavor.

Recent developments have undermined the authority of medical claims to expertise. Physician and nonphysician experts alike question the efficacy of particular medical procedures. Increasing numbers of clinical epidemiologists and others, often at the behest of governments, are busy formulating what medical procedures work and what do not. Even individual clinical work can be routinized through medical guidelines or protocols. In this respect, governments, seeking to rationalize care, are permeating and shaping medicine through the coop-tation of medical expertise itself.

In a neoliberal era, the drive by private and public payers alike to control costs has led to attempts to 'rationalize' care.

The current drive to reform health care has weakened the links between medical knowledge and medical authority both regarding medical control over health care systems and over clinical work. Economists, planners, and managers claim more expertise in health care policy than do physicians. State initiated medical protocols and clinical guidelines shape what doctors do in their day-to-day work. Some of these controls are aided by managers 'using' some physicians in managerial or scientific roles to help control others. There may be a restratification within medicine in which physician managers and academic and scientific medical experts are somewhat at odds with day-to-day practitioners.

The relationship between medicine and the social sciences has itself changed. Originally, medicine used the social sciences to accomplish its own tasks. Typically, social scientists were asked to help understand why some patients did not 'comply with' medical regimes. But the social sciences eventually began to take a more critical approach to medicine by challenging the biomedical paradigm, through their focus on medical power and self-interests, and for their support of the view that health is determined as much or more by social factors as it is by health care. Social science analyses once 'in' medicine are now mostly 'of' medicine.

The foundations of medical knowledge are also being challenged by new views of science in which knowledge is viewed as being socially constructed rather than science directly reflecting 'nature' (Lupton, 2000). Biomedicine is not viewed as scientifically neutral but as a truth claim among others in contests over power. From this perspective, the profession is also conceived as part of state attempts to control populations (Petersen and Bunton, 1997; Turner, 1995).

Medical Practice

Until relatively recently, doctors worked by themselves within private markets for health care. In the eighteenth and nineteenth centuries, doctor's care was often a last resort and hospitals were largely a place for the poor to die. In any event, few could afford physician fees. With improved perceived efficacy and the rise of a market for health care, physicians emerged as the preeminent free-enterprise professionals and adopted a corresponding individualist ideology.

In the twentieth century, as part of the movement toward the welfare state, the provision of medical care became a public concern. Internationally, many forms of payment mechanism and systems developed, from health care systems as in Britain to national health insurance as in Canada to more private and fragmented systems as in the United States. These systems influence what physicians do, where, and for how much (Hafferty and McKinlay, 1993; Johnson et al., 1995). Though medicine resisted the intrusion of state or corporate power or tried, with some success, to shape it, everywhere there has been more external influence than there was previously over the nature, conditions, and quality of practice.

Medical autonomy is being undermined in both private and publicly financed systems. In public systems, once some form of control over physician costs has been instituted, the state tends to leave purely clinical matters in the hands of the profession. Ironically, private systems may be more challenging to medical power than public systems because corporations are less open to medical political manipulation than are politicians. Yet, general government health care policies, such as the almost universal limitations over the use of technologies or payment methods, have a profound impact on what individual physicians do at the clinical level. More generally, state-profession relationships may now be characterized as 'mesocorporatist.' That is, in a number of jurisdictions the state seeks to use medical organizations to control medicine itself. For example, medical regulatory organizations depend on state power to control the body of the profession itself which in turn seeks to use regulatory organizations to control physician behavior.

The heart of professional standing is self-regulation, that is, the implicit promise by professions that, in exchange for extensive autonomy, the occupation will 'govern itself in the public interest.' Yet, within the market and outside of it, by competition, by corporate fiat and/or by state regulation, medical practice is subject to more surveillance and regulation including through reformed medical institutions of self-government. There is a deepening division in many jurisdictions between the function of representing the profession, the role of professional associations, and that of licensing and regulation, the function of medical 'colleges' or governmental institutions. Sensational examples of physicians abusing patients forced some governments, as in the United Kingdom, to constrain professional self-regulation which had failed to prevent medical crimes or misconduct (Dixon-Woods et al., 2011). Those medically dominated self-regulatory organizations that remain, even if still staffed mainly by physicians, are more constrained by public or governmental direction, regulation, or representation than they were previously (Allsop, 2006; Coburn, 1999). Just as medicine once permeated state centers of power in order to control health policy, now there is a major flow in the other direction, states shape medicine through coopting key medical organizations. Internal fragmentation made more difficult the efforts of medical elites to mobilize the profession to face its political, economic, and social challenges.

The last third of the twentieth century witnessed the rise of neoliberalism and globalization accompanied by attacks on the role of the state in the provision of social, health, and welfare services and the decline or transformation of the welfare state. This period was quickly followed by economic crises and austerity. Health care systems became more controlled, rationalized, and privatized. Under neoliberal regimes as in Britain in the 1970s, the professions were viewed as monopoly conspiracies against public 'consumers.' Though in various areas of the world neoliberalism is in decline, today business and states are in an implicit or explicit coalition to control health care costs and hence the work of physicians. Medical practice has thus historically moved from a situation of patronage, in which clients controlled physicians, to one of collegiate or colleague control in a medically dominated system, to one in which doctor–patient relationships are mediated by (public or private) third parties (Johnson, 1972). It has been argued that new forms of 'governmentality' involve states attempting to instill in both patients and providers new ways of viewing the self, that is, characteristics of self-responsibility and autonomy, which enables governments to escape from

actually providing necessary health resources and which shifts the political blame for health problems onto citizens themselves (Dent, 2006).

Understanding Medicine and Changes in Medical Power

What do developments in the last century and a half tell us about the medical profession? There is more agreement regarding the general trends than there is about how to explain these. Medicine rose to power in the nineteenth and early twentieth centuries. By the mid-twentieth century, medicine was one of the most powerful actors within health and health care. Other health occupations were absorbed, subordinated, limited, or excluded from the official health care system (Willis, 1989). Powerful within health care systems, medicine had important effects on the societies in which it was not only embedded but also reflected trends within the society of which it was a part. Yet, medical power was always contested and medicine was never all-powerful.

Today, however, medicine faces challenges from 'countervailing powers' (Light, 2010). Patients use unorthodox forms of healing, demand particular forms of care, and complain about or sue physicians. Health care occupations, from nursing to physiotherapy to chiropractic increasingly seek autonomy, and chip away at the borders of the medical monopoly. A proliferating variety of forms of unorthodox healing, from shiatsu to chiropractic, claim legitimacy in the 'system of professions' (Abbott, 1988; Saks, 1995). States and corporations, public and private payers come to shape medical work. The contribution to population health of a technologically sophisticated medicine, as opposed to improvements in living conditions, income equality or the social determinants of health, on human well-being or the health of nations is not as unequivocal as it once appeared. Moreover, just when medicine is facing external challenge, it is weakened by internal fragmentation by specialty and gender and by a developing hierarchy between an academic and research elite and practitioners. The major issue for social science analysts has thus become to understand a historical trajectory of rise, consolidation, and challenge or possible decline of medical power.

Some social scientists have used terms such as proletarianization or corporatization (McKinlay and Stoeckle, 1988) to depict trends diminishing medical power beginning in the latter part of the twentieth century. Proletarianization refers to processes similar to those that affected workers in the nineteenth century as skilled workers became employees and their work came to be controlled, routinized, and fragmented. Medicine, previously an autonomous and powerful profession has become subject to state, corporate, and bureaucratic imperatives. Though the term proletarianization is overdrawn at the very least, doctors now have to answer for the results of their work if not the processes involved, that is they are subject to processes of 'responsibilization' or 'performativity' (Dent, 2006).

A common-sense explanation for medical power is that medicine became authoritative as it gained in scientific knowledge and became more effective in curing disease. However, while improving effectiveness, or at least the perception of such efficacy, was important (doctors have to be sought out by patients), historians have noted that medicine became cohesive and dominant before it became more efficacious (Wailoo, 2004). Efficacy based theories of the rise of medicine also have difficulty explaining recent weakening medical power, though changing disease patterns from the predominance of infectious to chronic disease may be important.

Freidson's emphasis on medical dominance in the 1970s stimulated broader debates about the reasons for the rise of medical power but had little to say about future challenges. Pluralist interest group theories, or forms of Weberian-based closure theory (Murphy, 1988; Witz, 1992) which stress medicines' own struggles for superiority, contrast with structurally oriented theories which emphasize the rules within which interest group struggles occur (Abbott, 1988; Murphy, 1988; Navarro, 1976, 1988; Witz, 1992) or which contend that medical power is always subordinate to the power of dominant classes (Navarro, 1976).

Closure theory describes the strategies of demarcation of occupational boundaries and of exclusion used by medicine in attaining and maintaining its dominance over other health occupations as well as the contemporary struggles by other occupations to escape medical control. Closure theory though focuses almost entirely on interprofessional relationships, only one dimension of medical dominance. By contrast, structural theories claim that medical power is fundamentally anchored in the congruence of its interests and ideologies with those of dominant elites, industries, classes, and the state. Medicine in this view is a powerful intermediate source of power but not dominant. Navarro (1988), for example, argues that medicine was never dominant nor is it now being routinized. Rather, medicine, and a particular form of individually focused curative medicine, was preferred by a rising industrial capitalist class opposed to political movements pointing to poverty and poor working conditions as the source of illness. Individualist-oriented explanations drew attention away from the social causes of disease hence served the interests of industrial capitalists. Medicine's contemporary decline is also viewed in class terms involving a divergence between dominant class or corporate interests in saving costs and those of medicine to retain control over care (Coburn, 1999). A dividing line does exist between those social analysts focusing on a pluralist or power elite version of medical history and those paying more attention to class and capitalism as a mode of production. In general, more actor-oriented views imply that medicine imposed biomedicine on society, while structural analyses, whether power elite or Marxist, focus more on the 'selection' of a particular type of medicine by prevailing structures of power, class, gender, or race.

Any perspective on contemporary developments has to come to terms with broader economic and political developments accompanying change from the neoliberalism of the last quarter of the twentieth century to the economic and political crises of the early twenty-first century. In the social science literature, perhaps significantly, the medical profession and the concept of professional dominance are not as prominent as they once were – economic and political crises have pushed the fate of medicine onto the back-burner. Such a loss in centrality may also be another signal of declining medical power.

Conclusions

Medicine is like other forms of work and subject to many of the same general pressures. Physicians are both active in shaping and reproducing particular social structures yet the profession cannot escape being subject to external powers. Most recent social studies of the medical profession are oriented to its power, to changes in that power and evince skepticism regarding professional claims of altruism. The focus is on the self-interests of the profession and its changing accommodation with powerful social classes, elites, or institutions. This view contrasts with perspectives which emphasize the many individual (Norman Bethune in China) and collective (Medicine Sans Frontieres) acts of heroism and self-sacrifice of physicians or groups of physicians. However, the social science emphasis on self-interests and power is a little one-sided, medicine is not only self-interested. Moreover, a health care controlled by private corporations, managers, or the state, may presage a worse future for patients than one in which medicine, or at least individual physicians, retain a 'relative autonomy.'

Medicine rose during a particular period of industrial capitalism and flourished, perhaps had its golden age, during the period of the development of the welfare state at a time when working class pressures were at the height. In that milieu, medicine could partially reconcile both service to others and its own self-interests. We are today in a new era, one which began with a greater emphasis on individualism and on markets and is now enmeshed in crises in which corporate elites or classes are clearly in control, though not unchallenged. The ramifications of these changes for medicine imply greater constraints on medical prerogatives and do not presage a return to medicine's previous heights.

Medicine today is revered yet envied, sought after but viewed with skepticism, scientific yet collectively saturated with self-interests and motives not pregiven by its science or service, with many altruistic practitioners yet apparently mercenary organizations. The challenge for medicine is to fulfill its professional promise of service to others in an era of austerity, profit-seeking, and individual materialism. The social sciences focused on medicine are today in somewhat of a theoretical doldrums, still obsessed with medical dominance and interprofessional rivalries, but facing the broader task of providing an understanding of medicine more adequate to recent societal transformations and contradictions.

Abstract

Medical sociology builds on substantive areas of sociology. A dominant concern has been the distribution of health; illness and disability; services use; and class, race, ethnic, and age disparities. The field examines the organization and provision of service as shaped by culture, science and technology, and economic organization. The workforce, especially physicians, has been a core interest as has competition among professions for control over spheres of work. Other key areas include clinician–patient interaction and stress and coping. Attention focuses on the economic and ideological basis of U.S. health care, its exceptional expenditure levels and efforts to constrain costs.

Many individual sociologists in the first half of the twentieth century studied the distribution of illness, the plight of the sick poor, and physicians and other health care practitioners (Bloom, 2002), but medical sociology first emerged as a distinctive area of sociology in the 1950s, first in the United States, and later in many other countries. As a subdiscipline, it drew on the methodologies and middle-range theories of the three then-main areas of sociology: social organization, social psychology, and ecology and demography. Relevant subfields included social stratification, occupations and professions, political sociology, gender and race, complex organizations, deviant behavior, and socialization (Mechanic, 1978). Over the last half of the twentieth century, medical sociology came to share concepts and methods with related social and medical sciences including public health, health services research, medical economics, social epidemiology, health psychology, health geography, medical ethics, medical history and politics, and mass communications. As we proceed in the twenty-first century, the boundaries among the disciplines become more permeable and more blurred, and increasingly investigators study interconnections between social and social psychological factors and biological processes, including genetics, molecular biology, immunology, and psychophysiology.

Medical sociology from the 1960s in the United States developed rapidly, stimulated by the support of the National Institute of Mental Health (NIMH). The NIMH endorsed a public health approach to mental health issues and defined sociology as among the important basic sciences for mental health progress. The dominance of the NIMH funding helps to account for the disproportionate emphasis on mental health research in medical sociology's early development. By the late 1970s, medical sociology had become one of the largest sections of the American Sociological Association, exceeding 1000 members. In more recent decades, most institutes of the National Institutes of Health (NIH) have funded some medical sociological research and training.

Social Stratification and Health

A dominant theme in medical sociology has been the social distribution of health, illness, and disability and access to and use of relevant services. Much of the literature has focused on social class (usually conceptualized as socioeconomic status (SES)), gender, race and ethnicity, and age as associated with patterns of health and illness behavior, illness risk, distress and suffering, morbidity, mortality, and disability. On the services side, interest has focused on access to health care services, utilization of care, patient–clinician interaction, health outcomes, subjective well-being, and health-related quality of life.

Concerns with social stratification are now encompassed in the growing centrality of the field of population health (Mechanic, 2007), an interdisciplinary and cross-national endeavor to understand the determinants of health across geographic areas, nations, and cultures, with research focused on broad determinants, such as standards of living, poverty, inequalities, and globalization, to more microinfluences, such as nutrition, health behaviors, family structures, social networks, and social capital.

Socioeconomic Status and Health

Medical sociologists have given much effort to specify and test pathways through which social stratification, and especially SES, affects a range of health-related behavior, exposures to environmental risks, and mortality, morbidity, and other outcomes. SES, and its primary indicators, education, income, and occupation, consistently have been among the most powerful predictors of health care outcomes, such as maternal and infant mortality, chronic disease, disability, longevity, effective health behavior, and access to sophisticated and cutting-edge interventions. Much of the research in related fields as well as sociology has focused on specific risks and disadvantages correlated with SES as precursors to important health outcomes, but sociological work has persisted vigorously in the tradition of Durkheim seeking to elucidate distinctive sociological influences.

Link and Phelan's theory of social class as a 'fundamental cause' of health outcomes represents one such important effort (Phelan et al., 2010). They theorize that SES, and the power, money, prestige, information, and social connections associated with it, provide flexible resources that allow individuals and groups to be aware of health risks, live in environments and neighborhoods that protect against risk, take additional preventive actions when available, and have access

to high-quality interventions. SES is seen as fundamental in that while risk factors change over time, these flexible resources continue to provide advantage whatever the modifiable risks. Thus, they maintain, these resources allow control over a wide range of risks and diseases and are adaptable over time as risk factors and disease patterns change. Link, Phelan, and colleagues have derived a number of testable ideas from the theory of fundamental cause that provides greater explanatory power than risk factor theories that predominate in social epidemiology.

For example, Link, Phelan, and their collaborators observed that SES maintains its predictive effects over long time periods during which common risk factors change, that SES has little influence on nonpreventable disease, and that relevant health outcomes cannot be explained by measured intelligence, highly correlated with SES and commonly offered as an explanation for the predictive ability of SES.

Researchers have made efforts to establish which of the components of SES are most important for health. Although education, income, and occupation are highly associated, these factors are differentially important for varying health challenges. Education, for example, may be most important for the quality of parenting and protection of child health, while income is most important for quality of housing or neighborhood. In multivariate analyses, each additional component of social class commonly contributes additional explanatory power. From a sociological perspective, these indicators are proxies for theoretical conceptions of social class, which function more holistically to denote structural and hierarchical relationships.

Gender and Health

Gender as a major determinant of health encompasses the variations in biology, social roles, responsibilities, inclinations, normative behavior, styles of living, and interpersonal associations that differentiate the sexes. Sociologists have long been interested in the advantages in longevity that women in industrial nations have relative to men, their greater willingness to report illnesses and to use medical care, and many differences in illness trajectories. By way of illustration, I focus on two areas of persistent sociological interest, female advantage in longevity and the considerably greater prevalence of depression among women.

Women generally live longer in industrial countries than men with a pattern of favorable survival from birth onward. This is in contrast to some developing countries where males are much preferred and where selective abortion, differential feeding and nurturance, and even infanticide may favor males. Studies provide evidence for a biological advantage for women although many of the persistent sex differences can be explained by differential exposure to risk factors among men and women and stronger protective factors favoring women.

At the beginning of the twentieth century, average life expectancy in the United States was around 50 years with a female advantage of almost 3 years, but by 2006 expected length of life from birth had advanced to 75.1 years for men and 80.2 years for women. Similar patterns are evident in other industrial nations. In recent decades, however, advances in longevity in the United States while continuing, have not kept pace with many other industrial countries, and particularly for women. By 2007, expectation of life among American women (80.1), tied with Denmark for last place among 10 countries studied, ranging among the other eight nations from 86 in Japan to 81.7 in England and Wales. A recent study by the National Academy of Sciences of high-income countries, seeking to understand the relative American disadvantage, examined a range of factors to the extent that data were available, including smoking, obesity, physical activity, social networks, health care services received, hormone therapy, and inequality (Crimmins et al., 2010). The consequences of smoking which began earlier and more extensively in the United States was estimated to explain 78% of the female gap in life expectancy with other countries between 1950 and 2003, and 41% of the male gap. Although there is more uncertainty concerning obesity, data suggested that obesity in the United States also has had a significant role (Crimmins et al., 2010). Underlying these demographic analyses are the crucial roles of culture and social norms that have affected habit formation and its timing between men and women in different nations. Because smoking prevalence has fallen more sharply in the United States than other countries in recent years, we can anticipate the gap in smoking-related mortality to close in future years.

A large literature documents the higher prevalence of depression in women relative to men (in the range of 200–300%) in modern nations, and in many developing countries as well. The female excess is apparent by adolescence and continues throughout the life course. Although many hypotheses have been suggested and a variety of factors may be relevant, there is overwhelming evidence that social factors play a major causal role. A consistent pattern persists whether investigations examine depressive affect, clinical diagnoses of depression, help-seeking for depression, use of depression medications, or hospital inpatient admissions for depression. It appears that the excess prevalence of depression relative to men is balanced by excess prevalence of antisocial behavior, substance abuse, explosive behavior, and violence among men. These observations are consistent with a view that these two types of disorders, internalizing (intrapsychic pain) and externalizing (antisocial behavior), represent alternative modes of expressing distress and emotional tension and are not simply discrete entities each with independent causes.

Race and Ethnicity

Work in medical sociology has focused on disparities among the largest racial and ethnic subgroups in the United States: Caucasians, blacks, Hispanics, and Asians. Much of the literature rejects the construction of racial categories themselves and particularly those routinely used in national statistics and population studies. With greater understanding of population genetics, these conventional rubrics are seen as poor proxies for genetically distinctive subgroups. Moreover, the conventional categories themselves group heterogeneous and diverse subgroups that share little geographic propinquity or cross-breeding. For example, the Hispanic category spans diverse populations from Mexico, Cuba, Puerto Rico, Spain, and other Spanish-speaking cultures. Moreover, when focused on the U.S. population, added diversity comes from selective migration

that varies from one historical period to another such as the pre- and post-Mariel migrations from Cuba. Similarly, vast differences among blacks from varying regions of the world commonly are lumped into a single category. Occasional studies have the specificity and funding to examine the substantial subcategory variations, but most of the literature uses simple categorizations.

In the United States, race and ethnic categories are correlated substantially with SES. Because most categories mix high- and low-SES subgroups, and the mix often differs among geographic areas, there is limited consistency in research findings. The black population, especially in the United States, is an exception because of its protracted history of slavery, segregation and discrimination, and persistent poverty, resulting in consistent findings of high infant and adult mortality, chronic disease incidence, disability, and lesser access to high-quality health services. Despite efforts to diminish health care disparities, studies find poorer outcomes among blacks, even among those who have insurance coverage comparable with more privileged subgroups, attributable less to blatant prejudice and discrimination and more to how housing segregation of blacks funnel them to health facilities with less-sophisticated personnel and resources. Thus, differences in health and health care access are embedded in a larger configuration of poverty and geography (Sampson, 2012). An intriguing paradox relates to psychiatric disorders, which appear to be less prevalent among African Americans than other racial or ethnic groups despite their disadvantaged social position and unfavorable position on physical health indicators. Explanations vary.

A second ethnicity theme that elicits special interest is the relative favorable health status of Mexican Americans relative to Native Americans and other ethnic groups despite their disadvantaged socioeconomic circumstances. Conceptualized as the Hispanic paradox, considerable attention has been focused on alternative hypotheses involving selective migration, health-related behavior, family structure, and culture, among others. The immigrant advantage appears to dissipate in subsequent generations as native-born Mexican Americans acculturate to American and peer culture.

Age and the Life Course

Age, like gender, is important both as a biological and a social determinant of health outcomes over varying points in the life course. Age is strongly associated with the increased prevalence of chronic disease, particularly in later stages of the life course, although determinants often influence outcomes decades before illness manifestations, and even as early as prenatal and early life. Although increasing chronic disease in later life commonly has been viewed as a manifestation of aging, the common paradigm now distinguishes between the consequences of disease and the aging process.

The occurrence of chronic disease and disability in modern nations increasingly has been delayed by improved living standards, healthier lifestyles and behavior, and innovations in public health and medicine. This observation highlights the importance of the experience of varying birth cohorts who have different health outcomes at any given age reflecting the conditions affecting their social development, social and cultural changes, lifestyles and behavior, exposure to social and environmental trauma, and the vicissitudes of life under different historical, environmental, and political conditions. Although the trend in longevity generally has been upward in industrial countries, historical disruptions such as war and political disintegration, increased environmental threats, or changes in health behavior can reverse the pattern, as occurred in Russia after the fall of the Soviet Union. There is now speculation that changing social trajectories involving growing inequalities, environmental assaults, and changing health behavior (poor nutrition, lack of exercise, substance use, increasing obesity leading to diabetes and the like) could overtake medical progress and retard population health improvements. These observations make evident the extraordinary importance of culture, governance capability, and social capital in sustaining an upward course in population health (Kunitz, 2007).

Period effects in the evolution of populations are most difficult to model, including future threats such as war, thermonuclear accidents, climate change, terrorism, economic disruptions and depressions, deathly epidemics, or positive innovations that enhance opportunities for health advancement affecting aging and its quality. Most industrial nations, particularly European nations but also the United States, face aging populations with increasing proportions in the old–old age-groups in which frailty increases and cognition declines. All these nations face the economic challenge of maintaining a health and supportive safety net as the numbers of persons in their 80s and 90s continue to increase and as living arrangements and family structures change, making family caregiving more burdensome and less accessible. How varying nations respond to this growing population through support of alternative institutions depends on economic capacity, ideologies and values, and developing the appropriate institutional structures and workforce to respond meaningfully. It also will depend on the success of new innovations in computer applications, tele-medicine, robotics, nanotechnology, and increased knowledge and technology that will make frailty and dementia more manageable. The prediction that the mortality curve increasingly follows a rectangular pattern where successive cohorts experience a larger proportion of their life span free of disability before death remains to be substantiated but represents an aspiration in ensuring the quality of old age and the future abilities of nations to respond in a meaningful and humane fashion.

The Study of Health Care Organization and Provision

National systems of health care develop through their unique historical trajectories, national cultures, political systems and processes, and economic circumstances. Nevertheless, medical science and medical care, and the systems in which they are embedded, participate in worldwide networks and collaborations, sharing knowledge, technology, and organizational and economic innovations. In addition, common trends among modern nations in demography, urbanization, epidemiology of disease, rising public expectations, and the growing gap between medical possibilities and population demands, on the one hand, and the ability or will to fund them, on the other, pose many common problems for health care systems

(Mechanic and Rochefort, 1996). These problems include means of preventing illness and promoting health; organizing levels of health care and their interrelationships; expanding access to care; linking health and social services into more integrated patterns of care; improving the quality of services; monitoring system performance and health outcomes; regulating professional practice; ensuring the safety and efficacy of drugs and devices; and controlling costs and carrying out required rationing of care wisely and fairly. Most organizational studies of health systems bear on such problems as they relate to the organization of particular health care systems or subsystems. Although challenging, increasing efforts are made to study health systems comparatively across nations. Health knowledge, care provision, and its many complexities are part of a worldwide culture in which much learning goes on among nations, but ideologies and cultural differences often make rigorous comparisons difficult.

The Technological Imperative and Public Expectations

Among the most impressive medical developments in recent decades has been the growth of new technologies, devices and appliances, pharmaceuticals, and the like. Sophisticated advances in imaging, robotics, computer applications, nanotechnologies, prostheses, and more have fundamentally changed the potentialities and practice of medicine and surgery. Coincident with these developments has been the growth of large and powerful industries that have a powerful stake in how medical care is carried out and who spend many billions of dollars seeking to influence policy makers and regulators, physicians, other clinicians, and the general public. These developments are expensive and have contributed greatly to the challenge of increasing costs in all nations.

No nation is prepared to meet all clinician and patient demands for all possible interventions and every nation limits access and utilization in a manner consistent with its economic circumstances, political culture, demanding commercial and professional interests, and social ideologies. Most nations ration care more explicitly than in the United States depending on more centralized policy making on benefits, access, and provider payment, on the purchase and location of specialized facilities and equipment, and on cost–benefit analyses of the value of highly expensive treatments. In the United States, the concept of rationing is politically unacceptable, but rationing occurs in many ways, most obviously by making care and access dependent on insurance coverage, limiting the comprehensiveness of insurance, and the magnitude of copayment required of insured patients (Mechanic, 2006). Although many of the available treatment technologies are valuable in limited instances, the relatively high remuneration for procedural medicine encourages their use far more widely than justified. Industry hype and advertising increase public expectations of the value of technological interventions, and the marketing of new expensive modalities often contribute to misuse. Policy makers intervene cautiously on professional discretion and patient expectations, thus allowing unnecessary treatment and intractable growth in medical care costs. Many experts believe that overtreatment, waste, and fraud accounts for as much as a third to half of all care in the United States (Mechanic, 2006).

The United States is an outlier among nations in health expenditures spending double the proportion of gross domestic product (GDP) for health care than member countries of the Organisation for Economic Co-operation and Development , now approaching 18% of U.S. GDP. This is attributable to the U.S. commitment to a market-based system of care, the predominance of fee-for-service medicine, and much higher prices than elsewhere in the world for physician reimbursement, pharmaceuticals, and almost everything else. In 2010, the United States passed a major but highly controversial medical reform, the Affordable Care Act (ACA), which greatly expands insurance coverage and seeks to develop new ways to pay provider organizations and clinicians through financial incentives to provide high-quality and better coordinated care with less waste. Much attention has been given to elevating the role of primary medical care relative to specialist services, replacing fee-for-service medicine as much as possible with adjusted capitation approaches, including single payments for 'bundled services.' The legislation provides inducements for developing more integrated service provision through entities called accountable care organizations and medical homes by sharing savings derived from increased efficiency. Little about the ACA is certain at this time, such as the success of new organizations and incentives in reducing waste and lowering increases in the costs of medical care. Many of its other initiatives to prevent illness and promote health, to improve behavioral health care and integrate it better with general health care, to elevate primary care relative to specialty care, to build new medical care interdisciplinary teams, to improve chronic disease care, and to promote improved public health remain challenging. The legislation is extraordinarily inspirational, and if it resists repeal, it will require decades for full implementation. Among its provisions is a $10 billion fund to develop and study innovations. It leaves much for medical sociologists and other health services researchers to do.

The Changing Role of the Physician

Sociological work on the organization of care often has focused on the health professions – and particularly changing roles, the continuing struggle against dominance of physicians and their authority, intraorganizational networks and relationships, and the difficulties of integrating levels and sectors of care. There has been much interest in how incentives and other organizational characteristics affect processes and quality of care. Studies focus on a wide range of health organizations, including hospitals, health maintenance organizations (HMOs), large integrated multispecialty organizations, primary care practices, intensive care units, perinatal units, and nursing homes.

Much earlier sociological work focused on the medical profession and how it achieved dominance over medical work and public authority (Freidson, 1970; Starr, 1982). Although physicians remain extremely influential and highly trusted by the public, their dominance has eroded significantly since the 1970s. Sociological studies shifted from studying professional values and authority to more dynamic analyses of how professions and occupations compete to gain control over various spheres of work. With the growth of corporations,

including large insurers, health science centers, pharmaceutical and medical device industries, and a larger role for federal and state government – and as consumers gained power through disease advocacy organizations and access to information and communication channels through the Internet and other means – many strong competing voices have emerged on medical affairs and new coalitions seeking to influence policy. Associations and unions representing different groups in the large health workforce have helped to achieve greater independence and, in many cases, such groups (nurse practitioners, psychologists, or chiropractors) have gained recognition as independent practitioners and opportunities for reimbursement under private and government insurance programs.

The medical profession underwent extraordinary stratification with the proliferation of specialties and subspecialties and a continuing loss of relative status and income among those in primary medical care. Primary care became a disfavored career among graduates of U.S. medical schools and as primary care physicians were increasingly aggregated into larger medical groups, allowing fixed work hours and responsibilities, a greater proportion of women who were now flocking to medical school in proportions equal to men, were recruited disproportionally (Hoff, 2010). With the growth of the hospitalist who now increasingly manages inpatient care, and the economics of practice that made it inefficient for primary care physicians to manage a few hospital patients each day, primary care increasingly has become divorced from inpatient practice, which some see as 'dumbing down' the field. Increasingly, nurse practitioners, urgent care clinics, physician assistants, and behavioral health personnel compete for important components of primary care. Looking ahead the aspiration is to remake primary care within a comprehensive, integrated system of care that coordinates the wide range of services and specialists patients now use, that addresses chronic disease and its many aspects through teams, and that brings together the physical and behavioral care needed by patients with complex comorbidities. Much research now is focused on understanding how these organizations can be best organized and remain economically viable within the concepts of medical homes and accountable care organizations, and the potential for a more effective and meaningful primary care system.

The Intractable Cost Crisis and Managed Care

Managed care has a long history in Europe through general practitioner gatekeepers, remunerated by capitation, who controlled access to hospital and specialty care and other expensive care modalities and who had no financial incentive to overtreat patients. In the United States, however, fee-for-service predominated, and many studies showed how incentives in payment encouraged unnecessary services and cost. Particularly successful were some large multispecialty group organizations organized around prepayment like Kaiser-Permanente (K-P), an integrated health care program serving more than 8 million people. Studies found that such systems provided comparable or better care than private fee-for-service practice in their geographic areas at lower cost. As costs became an increasing concern, and with the failure of the Clinton health care plan in 1994, the private sector organized a variety of prepaid organizations and managed care approaches seeking to control costs. Organizing the K-P type of practice, sources of most of the favorable research, required considerable capital and organizational capacity, and such closed practices were resisted by many patients who did not want to leave ongoing physician relationships or be locked into a closed physician roster.

Insurers developed a variety of alternative models of managed care, most referred to as HMOs or network models that share some common strategies, such as the use of capitation payment and transfer of risk through organizational levels, the use of utilization review to limit the provision of 'unneeded' care, and new systems of constraints on physicians, including practice guidelines, disease management programs, and physician profiling. Most of these new organizations were virtual HMOs in that physicians typically provided care in their usual patient offices and, unlike K-P, served both capitated and fee-for-service patients. Insurers also rapidly developed preferred provider organizations (PPOs) that provided insured patients with a panel of physicians who agreed to provide services at the insurer's reimbursement rate with either no or modest copayment by the patient. When patients used physicians outside the panel, however, they were required to pay a larger proportion of the cost. Researchers found that although they rarely achieved cost and outcome advantages comparable to large integrated prepaid plans, they provided similar services to traditional fee-for-service medicine at reduced cost.

Many physicians and their patients disliked the requirement to get approvals from utilization reviewers and other types of explicit rationing that made it apparent at the point of service that interventions they and their doctors wanted could be denied by the insurer. Physicians also disliked the reduced payment for services and other directives and constraints and organized a strong backlash against many of these management practices. Although initially costs were substantially controlled under strict management, insurers backed down under pressure, litigation, and bad publicity and substantially reduced the strictness of reviews, what analysts came to call 'managed care lite'. The consequence, also, was less success at controlling increased costs.

Management limits were reduced in the case of medical and surgical services, but strict managed care continued in behavioral health care, often administered separately from medical or surgical coverage, by 'carving out' behavioral health and contracting with private managed behavioral health care organizations to manage these services.

In many ways, current efforts to move to new types of reimbursement like bundled payment and payment by episode is a return to the incentives of capitation, seeking to reduce the tendency to generate services to increase income. The aspiration is that by linking this to monitoring of quality, and paying physicians bonuses for good performance, the major disadvantage of capitation to incentivize withholding useful services will be mitigated. This remains to be studied as these new approaches are implemented.

Social Psychology of Health and Health Care

There is a long-standing interest in medical sociology and social psychology in microsocial processes. Such areas as doctor–patient interaction as well as the stress, coping, and social support

processes are perhaps the best integrated bodies of knowledge tied to common theoretical interests and methodological concerns. These interests are shared by other disciplines as well, such as psychosocial epidemiology and health psychology.

Clinician–Patient Interaction

Although the financial and organizational structures of care are crucial, for most patients, what counts most is their personal experience with their physicians, how much they believe they can trust them, the quality of care and caring they believe they are receiving, and their outcomes. There is now a massive literature on doctor–patient relationships, patient–clinician expectations, determinants of trust, quality of communication and instruction, and outcomes of shared decision making (Roter and Hall, 2006). Disparities in access, satisfaction, trust in medical care, and outcomes vary among race and ethnic groups, stimulating interest in understanding the sources of these gaps and whether similarities in background, culture, and attitudes among patients and clinicians mitigate these variations. Aspects of this concern include issues of cultural competency and medical literacy.

From patients' perspectives, paramount concerns are clinician competence and caring, and the extent they perceive clinicians are committed to their interests. Competence typically is assumed and generalized from the ways the clinician interacts, listens, and responds appropriately to questions, provides coherent instructions, and demonstrates interest in the patient's understanding. Microstudies of such interactions monitor such behavior as listening, responding to questions, providing information, interrupting patient communications, distracting behaviors, eye contact, and nonverbal communication.

Stress and the Coping Process

This health paradigm posits that stressful life events cause negative health outcomes when individuals or groups lack the counterharm resources necessary to deal with the stressors, such as ability to deal with the instrumental challenges and to successfully manage the emotions elicited (Mechanic, 1978). Social support buffers the effects of the stressor, often has a direct effect on outcomes, or both. Other important moderating effects include one's sense of personal efficacy embodied in measures of personal control, mastery, or low helplessness. Attributional factors also are important, such as whether the cause of the difficulty is seen as internal to oneself or due to independent events. Over the years, many models have elucidated pathways in the stress process and the relative influence of varying intervening or moderating factors. More recent studies link studies of the stress process with psychophysiological and immunological measures, and brain imaging, demonstrating the complex relations among perception, behavior, and biological processes.

Many important questions persist in the stress-coping literature despite large advances in measurement, data quality, and analysis. Much debate continues on the role of meaning, how it should best be measured, and its importance in response to potential stressors. It is difficult empirically to capture the fact that many stressful life events are not single occurrences but rather are part of a sequence of interconnected stressors with important feedback effects. In the area of social support, researchers are now more aware that people who wish to or attract support are different than those who do not, and that such selection is evident even early in life. Thus, it is important to distinguish between the effects of support from the personal attributes that draw support from others. There is also now greater attention to the fact that supportive relationships carry reciprocal obligations that can induce significant stress.

Social Networks and Social Influence

Social support at the individual level is a source of information, instrumental assistance, and affection and intimacy. An individual's location in a larger network of both strong and weak ties encompasses different opportunities and influences. Although earlier literature focused on primary group ties, which are a strong source of meaning, affection, and assistance, understanding the increased range of weak ties that links with broader perspectives and opportunities, such as the availability of a needed job, captures a much broader field of influence.

With the growth of improved data sources and the power of computing, it has become increasingly possible to map extensive social network and their influence on habits, preventive health behaviors, and a wide range of other social responses. Network influences have been shown to affect smoking patterns, weight gain, and obesity, and information on how to access varying services, including medical care (Christakis and Fowler, 2009). Opportunities for tracking complex networks suggest new ways of using social network theory and methodology to achieve desired health behavior and outcomes.

Neighborhood Influences

As population health perspectives have gained prominence in medical sociology and the importance of place has become more widely appreciated, research has increased on how neighborhoods shape health opportunities and threats. An obvious deterrent to disentangling the characteristics of people selected into neighborhoods from the impact of place itself are the continuing ways in which people select into and out of neighborhoods. Greater availability of longitudinal data and multilevel modeling make this challenge more tractable, and there is growing credible evidence of neighborhood effects that transcend the effects of the characteristics of people and their choices. There is also persuasive evidence of how population characteristics of neighborhoods, and especially race and poverty, and how residents perceive the order of their neighborhoods, are associated with various indicators of health and welfare (Sampson, 2012). Finally, an extraordinary randomized study, Moving to Opportunity (Ludwig et al., 2011), which provided opportunities for poor families to improve their housing by moving to housing in better neighborhoods, demonstrated both the complexity of the person–neighborhood interaction, and illustrated how such change potentially can improve child health status.

Disability and Quality of Life

In the past several decades, medical sociologists have contributed importantly to understanding determinants of disability

and how individual and social definitions of bodily impairments, and social constructions about the agency of persons with these impairments, can lead to widely varying outcomes dependent on social expectations, public attitudes, social norms, and the regulation of the built environment. Sociological work in this area contributed much of the theoretical basis that inspired U.S. legislation affecting people with disabilities and the societal resources made available.

Sociological work made evident that disability that commonly was seen as an incapacity of the person was more properly conceptualized as an interaction between an impairment and the environment. The extent of disability experienced was dependent on the housing, transportation, and other accommodations that either were facilitators or barriers to participation. Changes in attitudes, physical arrangements, and social expectations greatly expanded opportunities for people with impairments to participate in social life from work to athletics. Many studies documented how people with even the most severe physical and emotional impairments could participate in work and other activities to an extent hardly imaginable 50 years ago.

The past 50 years during which medical sociology developed as a major area of inquiry has seen a transformation in the health and aging of the population. On the one hand, people have lived longer and healthier lives and have had opportunities to participate more fully in social life. The health enterprise has expanded enormously, and although sociologists are concerned with increasing medicalization of ordinary problems of living, overdiagnosis, and overtreatment, there is little question that medical developments have contributed meaningfully to people's lives. On the other hand, growing rates of obesity, the large numbers of people with chronic disease, the growing prevalence of Alzheimer's disease and other dementias among the elderly, and increasing rates of autism and other developmental disorders, among many other problems, indicate that enormous scientific terrain remains to be plowed and many opportunities are yet to be explored for promoting health and welfare. As René Dubos sagaciously noted, the idea of health perfection is a mirage, and the environmental and social conditions we create inevitably bring new diseases and bodily assaults. At best, we achieve greater understanding that allows us to ameliorate threat and enhance the opportunity of each person and population group to achieve the highest quality of life in their circumstances.

Abstract

Medicalization is the process by which nonmedical problems become defined and treated as medical problems often requiring medical treatment. The term medicalization first appeared in the sociology literature and focused on deviance, but it soon expanded to examine other human conditions. This article focuses on sociological and anthropological perspectives on the expansion of medicalization. This includes a review of the characteristics, origins, and consequences of medicalization, with sociology's emphasis on the emergence of medical categories and anthropology's emphasis on biomedicine's institutional power and cultural authority. Medicalization has numerous social consequences, including the pathologization of human differences and individualization of human problems while minimizing social and political context.

Sociological Roots

Medicalization means 'to make medical' or more specifically the process by which previously nonmedical problems become defined and treated as medical problems, usually as diseases or disorders. Social scientists and critics including Foucault (1965), Szasz (1970), and Illich (1976) criticized medicalization for its potential to serve as a mechanism of social control, although they did not use the term. Jesse Pitts (1968), in an earlier edition of a *Social Science Encyclopedia*, wrote specifically and largely positively about the medicalization of deviance, relating it to changing forms of social control. It was Zola's (1972) paper that became the touchstone for medicalization in sociology, where he too focused on the expansion of medical social control. Shortly thereafter, Conrad (1975, 1976) and Conrad and Schneider (1992) wrote specifically about various aspects of the medicalization of deviance. Research on medicalization expanded from a focus on deviance to a broader lens of life conditions and ailments. Since those early works literally thousands of papers have been written on medicalization (e.g., see Clarke et al., 2011; Conrad, 2007) by sociologists, anthropologists, historians, feminists, and medical scholars. Medicalization has become a common term in the social science and medical literature and to a degree in the public media.

The focus of medicalization is on the process by which human problems or conditions become defined and treated as medical problems. While some critics have used the term medicalization synonymously with 'overmedicalization' (too many diagnosed or medically treated), there is nothing inherent in the sociological analysis of medicalization that necessarily suggests an evaluation of medicalization. Rather, medicalization is a phenomenon that can be examined the way other 'zations,' such as industrialization, urbanization, or secularization can be analyzed – as a process to be understood in its own right (Conrad, 2013). The most common sociological perspective for examining medicalization is as a form of social constructionism (Conrad and Barker, 2010), although some analysts have suggested a broader perspective under the term biomedicalization (Clarke et al., 2011).

Characteristics of Medicalization

There are several characteristics of medicalization. (1) The definitional issue is central to medicalization; that is, how a problem is defined is key to what is to be done about it. (2) There are degrees of medicalization. For example, some problems are almost completely medicalized (e.g., schizophrenia, epilepsy), while others are only somewhat medicalized (e.g., Internet addiction, sexual addiction), with still others contested or somewhere in between (e.g., obesity, opiate addiction). Thus medicalization is more of a continuum than a binary either/or distinction. (3) Medicalized categories can expand or contract. For example, attention deficit hyperactivity disorder (ADHD) was for many years seen as a disorder of children but it is now seen as a lifespan disorder, including adult ADHD. Posttraumatic stress disorder emerged in the 1970s as a diagnostic category depicting Vietnam veterans and has expanded to include survivors of violence, sexual abuse, or natural disasters. Now it can even be applied to individuals who have witnessed violence or disaster. On the other hand, hysteria, which was a common medical category in the late nineteenth century, has almost disappeared as a diagnosis. (4) Physician involvement in medicalization is variable. With the medicalization of alcoholism, physicians were minimally involved; rather, the emergence of Alcoholics Anonymous was central to this process. With many other examples of medicalization, direct medical involvement is a key. (5) Medicalization is bidirectional; that is, there can be medicalization as well as demedicalization. The most common example of demedicalization has been homosexuality, which due to the 1974 vote of the American Psychiatric Association and subsequent changes became 'officially' demedicalized (Conrad, 2007). There is no question, however, that there has been much more medicalization than demedicalization in the past four decades. One recent study (Conrad et al., 2010) estimates

that medicalized disorders cost about $77 billion or about 3.9% of our health care expenditures, more than is spent on all of US public health.

Caveats about Medicalization

A few caveats about medicalization studies should be noted: (1) Some researchers focus on whether medicalized problems are 'real' diseases or whether they are socially invented medical categories. It is important for social scientists to remain agnostic on what is or is not a 'real' disease; a better question to ask is how did this problem become defined as a medical disorder and with what consequences? (2) Much of the popular and some of the academic writing on medicalization has been concerned with the 'overmedicalization' of society. While considerable research on medicalization does suggest potential overmedicalization is an issue to be considered, medicalization studies focus on the 'process' of medicalization and are not necessarily driven by concerns of overmedicalization. Sociologists study medicalization just like they study other social processes, focusing on the origins and consequences of the phenomena. It is probably likely in some cases that there has been an overmedicalization of some medical problems, while in others undermedicalization of a certain problem may be the case. (3) Occasionally, critics will use the term medicalization as an epithet or pejorative, with the assumption that medicalization is by its nature a 'bad' thing. But as we have emphasized, medicalization is not a normative process, in itself neither bad nor good. Historically, for instance, there are many examples of beneficial medicalization, such as epilepsy and, in important ways, childbirth. It is hard to imagine that most people would prefer to return to the era when epilepsy was seen as possession or a 'curse,' a sign of being bewitched and a justification for institutionalization; nor would we want to revisit a childbirth era in which maternal mortality was common and infant mortality was a regular birth outcome. That is not to say that feminists and others have not provided important analyses of some of the consequences of what might be called the unreflective and extreme medicalization of modern childbirth, such as the very high rate of caesarian sections in the United States and elsewhere (Morris, 2013).

Anthropological Perspectives

While sociologists may have pioneered studies in medicalization, other disciplines (e.g., history, bioethics, medicine) have made important contributions to the medicalization literature. Most notably, the number of studies and statements regarding medicalization has grown in the field of anthropology. This is especially the case in the subfield of medical anthropology – where considerable attention has been given to the ways in which disease and disease-like states are created (Cohen, 1998; Lock, 2001), and the effects of such processes on people's lived experience.

Together with sociologists, anthropologists in the 1970s and 1980s often described medicine as an institution of social control, with health professionals acting as the agents of such control (Lock and Nguyen, 2010: p. 70). Numerous anthropological studies depicted physicians as aggressive medicalizers (Lock, 2001) and great attention has been paid to "the power of clinicians who wield biomedical discourse and technologies in constituting illness, in 'making medical'" (Crowley-Matoka and True, 2012). A turn in recent decades toward critical medical anthropology emphasizes power relations that affect biomedicine, often critiquing biomedicine's dominance over alternative health systems, the power structures existing within biomedicine, and marginalized populations' lack of fair or equal access to biomedical options (Baer, 2004; Singer, 1989, 1990).

Anthropologists continue to explore how the modern medical profession amasses and uses its power and authority (Behague, 2009). Anthropological studies have provided important insights into how biomedical perspectives and treatments are applied to numerous aspects of human life, often in non-Western settings. They have also emphasized individual's responses, experiences, and meaning making with respect to processes of medicalization. Such emphases differ at times from a stronger tendency within sociology to explore the emergence and development of medical categories (e.g., diagnoses) as well as their application. In contrast to anthropological literature, much of the sociological research on medicalization also continues to focus on Western populations and groups.

Ethnographic research, the cornerstone of many anthropological as well as sociological studies, provides rich insights into the diverse responses – individual, family, and community – to medicalization. Ethnographic and other qualitative research approaches are well suited for capturing thick descriptions of people's perspectives and lived experiences (Geertz, 1973). Lock (2001: p. 482) describes how the complexity of responses to medicalization necessitates the use of an "approach that is sensitive to the situated exigencies of the everyday worlds of informants and their relationships within families, communities, and local political groupings." The following sections provide examples of some of anthropology's contributions to the medicalization literature.

Medicalization and Mental Health

Anthropological studies contribute to a growing body of scholarly literature on medicalization and mental health. Sociologists and anthropologists have made important contributions to understanding the medicalization of mental disorder (e.g., Behague, 2009; Conrad and Slodden, 2013; Horwitz, 2002; Horwitz and Wakefield, 2007; Lane, 2007) revealing medicine's widening jurisdiction over mental facets of life (e.g., behaviors related to attention, sadness, shyness). For example, reflecting upon the American Psychiatric Association's designation of grief as a diagnostic category in the diagnostic and statistical manual–fifth edition, Kleinman (2012) cautions against turning ordinary bereavement into an appropriate target of medical intervention. He describes the medical profession's ability to reframe experience in ways that can influence culture change, for example, around death.

Alongside sociologists and historians, anthropologists emphasize how medical models of causation ignore sociopolitical context and individualize aspects of mental health

(Behague, 2009; Conrad and Slodden, 2013; Horwitz and Wakefield, 2007). Scheper-Hughes (1992), for example, showing how hunger and related distress, or *nervos*, in Northeast Brazil, were medicalized and treated through medical interventions such as pharmaceuticals rather than through social and political reform.

Debates have also emerged within anthropology and sociology on medicalization and psychiatry about how to move beyond a polarity between scientific objectivism and social constructionism (Behague, 2009). Some scholars point out that research grounded within social constructionist frameworks, while providing important insights into subjective experience, dislocate such subjectivity from broader contextual factors (Behague, 2009; Butt, 2002). Such views reflect more general issues in the field about a need to explore both micro- and macrolevel contexts, individual experiences and social relations, local contexts as well as broader political and economic forces (e.g., Scheper-Hughes and Lock, 1986; Singer, 1989; Taussig, 1980).

Medicalization and Women's Health

The anthropological literature is also replete with studies of the medicalization of women's bodies and health (e.g., fertility, pregnancy, childbirth, menopause) (see Behague, 2002; Davis-Floyd and Sargent, 1997; Ivry, 2010). Hunter de Bessa (2006: pp. 221–222) notes, for example, that "aspects of reproduction once thought to be primarily political, personal, or social in nature have come to be seen as medical problems – problems that are thought to be best solved by physicians through medical practice and management." Anthropologists have explored how (e.g., via cesarean section or natural birth), where (e.g., in a hospital or at home), and when (e.g., prolonged pregnancy and induced labor) women give birth, as well as the ideological and sociocultural frames which may influence such decisions (e.g., Behague, 2002; Davis-Floyd, 2003; Donner, 2003; Westfall and Benoit, 2004). They have studied women's fertility (e.g., Becker, 2000; Ivry, 2010), including research on domestic and transnational assisted reproductive technologies and their markets (e.g., Franklin, 2011; Inhorn and Gurtin, 2011; Inhorn and Patrizio, 2012; Morgan and Michaels, 1999). They have also described how resistance to medicalization contributed to the emergence of the home birth movement and the use of alternative therapies (Davis-Floyd, 1993, 2003; Lock and Nguyen, 2010).

An important line of anthropological research connects feminist critiques of the biomedical profession's power, particularly over women's health. Medicine has been described as a deeply patriarchal institution that views the female body as a vessel upon which to intervene with various – often reproductive – technologies (Davis-Floyd, 2003; Hunter de Bessa, 2006; Lock and Nguyen, 2010). Feminist anthropologists have drawn attention to the potential negative consequences that medical technological advancements and 'an ethos of intervention' can have on women's health and human rights (Hunter de Bessa, 2006). Some scholars have also cautioned against depicting women in passive roles – arguing that such depictions perpetuate the very kind of assumption that feminists have been trying to combat (Lock and Nguyen, 2010).

Anthropological studies describe women's diverse responses to medicalization (Hunter de Bessa, 2006) including showing that women are not always victims or passive recipients of medicalization (Lock, 2001; Hunter de Bessa, 2006). Martin's (1987) study of women in Baltimore, Maryland, revealed that they may resist and form meanings that vary from those which are dominant in the medical profession. Women may also embrace medicalization and medical technology as enabling, particularly with respect to infertility (Becker, 2000; Kielmann, 1998) or use technology to seek some degree of advancement or independence for themselves (Lock, 2001; Nahman, 2011; Pande, 2010). Women's behaviors may stem from a desire to satisfy, or respond to pressure from others (e.g., family members, women's groups, their community) (Lock, 2001). Individual responses to biomedical technologies are often pragmatic; they are based upon what individuals perceive to be in their own, their families' or their communities' best interests (Donner, 2003; Lock and Kaufert, 1998; Lock, 2001). Anthropological studies also emphasize the role that ideology, irrespective of medical necessity, may play in shaping reactions to medicalization (Behague, 2002; Donner, 2003) and the intricate relationships between ideology and forms of social inequality which may shape responses (Behague, 2002). Such insights shed light on the complexity of responses to medicalization and complicate our notions of resistance, agency, and autonomy (Lock, 2001).

Social Consequences of Medicalization

Both anthropologists and sociologists have described various social consequences of medicalization, including how, by extending the sick role over a broader range of human conditions, medicalization can excuse an individual from social roles and expectations (e.g., related to school, work, caregiving) (Lock, 2001; Scheper-Hughes and Lock, 1986). As Lock (2001) indicates, at times, medicalization can function to 'exculpate individuals from responsibility for being sick.' Along with historians and sociologists, anthropologists have also shown how, with medicalization, attention may be deflected away from the sociopolitical and economic context that influences matters related to health, prevention, and treatment (Lock, 2001; Marshall, 2005).

Anthropological researchers suggest that subjectivity and the reporting of symptoms are 'subsumed into medical pathologies and standard deviations from medical norms,' while attention and responsibility are placed on individuals and their bodies (481). Sociologists, focusing on the emergence and treatment of diagnoses such as ADHD, mild depression, obesity, and menopause (see Conrad, 2007; Horwitz and Wakefield, 2007), have expressed concerns about the pathologization of everything, that is, turning all human differences into diagnoses and treatable disorders.

Much anthropological research on medicalization explores the perspective and lived experience of individuals whose health may be affected by processes of medicalization. For example, Wentzell's (2013) ethnographic research

revealed how older Mexican men resisted a medical model of aging and its associated antiaging interventions by rejecting the use of erectile dysfunction drugs. Men framed decreased sexual activity as a means of fulfilling socially valued gender norms.

Anthropological studies of physicians often focus upon their hegemony over knowledge without exploring their subjective experiences. Several recent studies mark exceptions to this trend. For example, Crowley-Matoka and True's (2012) ethnographic study of clinician's perspectives suggests that incomplete and ineffective medicalization of pain and its management may lend to disempowerment – for both patients and clinicians. Ivry (2010) describes how in negotiations between medical professionals and rabbinic authorities over matters of fertility assistance, religious law and authority could be mystified by both parties in such a way that led many physicians to feel helpless. Such works call into question well-established notions about power and control in the medical profession.

Additional Uses of Medicalization

In a few cases, the term medicalization itself has been used to mean more medical involvement, attention, or concern as in a particular area. While these works use the term medicalization, as in 'The Medicalization of Anthropology: A Critical Perspective on the Critical-Clinical Debate' (Morgan, 1990) or The Medicalization of Cyberspace' (Miah and Rich, 2008) they use the term to mean the increasing medical concerns among anthropologists or the expanding medical attention on the Internet. Speaking more specifically of the subfield of medical anthropology, Browner (1999) describes a 'medicalization of medical anthropology,' by which she means increased attention within the field to the study of 'entities as they are conceptualized by biomedicine.' Browner describes how medical anthropologists are increasingly taking jobs in the United States, not in basic research, but in work that is based in facilities that provide medical care. Such trends need not necessarily be positive or negative, she notes, but there are potential substantive and methodological consequences, which may result from a field that is increasingly medicalized. Browner (1999) cautions against uncritical acceptance of biomedical explanations and categories for illness, and points to potential challenges associated with aligning hallmark anthropological research methods (e.g., ethnography) with 'a circumscribed biomedical condition.' These uses of the term medicalization, however, are different than the analysis of the development of medical categories or the use of medicalized conceptions presented in this article.

The term medicalization has in the past four decades become an important concept in the social scientific studies of medicine. An increasing number of researchers in the fields of sociology and anthropology, as well as history, bioethics, and medicine are both using the term and conducting research in the area. Given the continuing expansion of medicine in the twenty-first century and the exportation of Western medical categories (i.e., diagnoses, treatments) as part of the globalization of biomedicine, one can predict that medicalization will continue to expand and be of major interest to social scientists.

Medicine and Health for Sexual Minorities

Abstract

Over the course of the last 40 years, lesbian health has been an evolving concept. Emerging from the alleged neglect of lesbians in the women's health movement, lesbian health has become an institutional specialty, a research subject, and a social movement. Although lesbian health has gained a great deal of attention, just who counts as a lesbian remains in flux.

In 2010, the US Department of Health and Human Services (DHHS) articulated its national health goals for the next 10 years in its Healthy People 2020 program. One of its new initiatives was the goal of improving the "health, safety, well-being of lesbian, gay, bisexual, and transgender (LGBT) individuals." Justifying this focus, the government cited research demonstrating that "LGBT individuals face health disparities linked to societal stigma, discrimination, and denial of their civil and human rights." It maintained that discrimination led to "high rates of psychiatric disorders, substance abuse, and suicide." Efforts to improve LGBT health focused both on improving the clinical climate and the larger social and cultural environment for LGBT individuals. (HealthyPeople.gov. www.healthypeople.gov/2020 (accessed 25.06.13.).)

The inclusion of LGBT health needs in Healthy People 2020 is the culmination of 40 years of activism to better identify and meet the changing health needs of gay, lesbian, and transgendered people. Its inclusion, however, presumes a questionable intellectual coherence to LGBT health needs, and obscures the distinct paths the members of the LGBT communities have forged as they struggled to gain attention to their particular health needs.

This article focuses on the history of 'lesbian health' in its many guises: as an area of unmet need, an institutional specialty, a research subject, and a social movement. It shows how 'lesbian health' emerged out of two overlapping social movements, the women's health movement and the gay liberation movement. It also demonstrates that 'lesbian health' has always been a category with fuzzy boundaries, shifting content, and complex politics. This history also highlights several concerns still at play under the rubric of lesbian health. Who is the target for lesbian health interventions? Is lesbian health best understood as a subset of women's health, LGBT health, or as a separate entity? How has the changing social climate influenced lesbian health needs? Are lesbian health issues largely social and economic, the consequences of discrimination, or are they primarily embodied? The roots of many of these questions emerged with the concept in the early 1970s and remain unresolved in the twenty-first century. The inclusion of lesbian health as a Healthy People 2020 goal demonstrates its emergence and tenacity as a pressing issue, but its history highlights its shifting scope.

Radical Health Movements: The Context for Lesbian Health

The long 1960s and 1970s are well known for a variety of social movements that demanded a profound reorganization of the social and cultural fabric of the United States. These included the civil rights movements, the student movement, and the antiwar movement. The women's rights movement and the women's liberation movement emerged out of this widespread social ferment.

In broad strokes, the women's rights movement sought to equalize the educational, professional, and political opportunities for women. It tended to focus on change within the system, promoting for example, the Equal Rights Amendment, Title IX, and equal pay provisions. On the other hand, the women's liberation movement, identifying patriarchy and sexism as the primary oppressors of women, called for a more profound reconceptualization and reorganization of society. Believing that the Personal was Political, the women's liberation movement promoted consciousness raising, zap actions, and female-centered alternatives to male-dominated institutions. The issue of sexual identity in these branches of the women's movements was sometimes fraught. Although lesbians actively participated in both the rights and liberation movements (indeed, many lesbians were created through these feminist movements), lesbians frequently felt their concerns were overlooked in the agenda of straight (often white) women. (Echols, Alice, 1989. Daring to Be Bad: Radical Feminism in America, 1967–1975. University of Minnesota Press, Minneapolis; Enke, Anne, 2007. Finding the Movement: Sexuality, Contested Space and Feminist Activism. Duke University Press, Durham; Radicalesbians, 1972/1992. Woman-identified woman. In: Jay, Karla, Young, Allen (Eds.), Out of the Closets: Voices of Gay Liberation, second ed. NYU Press, New York, pp. 172–181.)

The gay liberation movement similarly emerged from these civil rights, antiwar, and student movements. In the late 1960s, the older homophile movement was supplanted by a distinctly different movement that rejected the politics of respectability, instead demanding recognition of sexual and gendered behaviors outside the norms of the middle-class, white mainstream. This gay liberation movement did not dismiss the homophile movement's focus on the rights of gay and lesbian people, but it created an in-your-face demand for cultural

recognition. Gay liberation celebrated sexual freedom, encouraged 'gay pride,' and demanded respect for gender nonconformity. In gay pride parades, openly gay community establishments, and artistic creations, gay men and lesbians fought for their rights by living out loud.

The boundaries between the women's liberation movement and this gay liberation movement were not clear, particularly when it came to lesbians. Some lesbian activists believed that their oppression was grounded in sexism, heterosexism, and homophobia, so they simultaneously worked through both movements. Similarly, lesbian feminists, working both inside and outside of feminism, shaped the agenda of the women's liberation movement in significant ways.

The women's movement and the gay and lesbian movement both had factions that focused on health. From safe and legal abortions to convenient and effective methods of birth control, from natural childbirth to sexual self-determination, feminists insisted that the ability to make decisions about their bodies provided the essential foundation for the larger liberation of women. By the late 1960s, this attention to women's bodies had coalesced into a women's health movement. (For general histories of the women's health movement, see Ruzek, Sheryl Burt, 1968. The Women's Health Movement: Feminist Alternatives to Medical Control. Praeger Publishers, New York; Kline, Wendy, 2010. Bodies of Knowledge: Sexuality, Reproduction, and Women's Health in the Second Wave. University of Chicago Press, Chicago; Morgan, Sandra, 2002. Into Our Own Hands: The Women's Health Movement in the United States, 1969–1990. Rutgers University Press, Brunswick.)

In general, health feminists identified sexism and patriarchal dominance as the root of women's oppression. (These activists were not blind, however, to the role of racism, capitalism, and imperialism in securing and maintaining women's oppression.) To combat the sexism and oppression that harmed women's health, health feminists were generally guided by three principles. First, health feminist insisted that women rather than men – whether in their roles as physicians, legislators, or spouses – should be in charge of women's bodies. Women should decide for themselves how to control their fertility, express their sexuality, and cope with their illnesses. Second, the movement insisted that women had the right to participate actively in the doctor–patient relationship, rejecting the patronizing and paternal cultural and professional assumption that 'the (male) doctor knows best.' Health feminists demanded access to information about their bodies, healthy and ill, and to participate fully in their health care decisions. Finally, health activists argued that physicians had taken over many bodily events (menstruation, childbirth, and fertility control) that should not be considered 'medical' in nature. Women active in the movement sought to return these women's health matters to women's hands.

The self-help gynecology movement, one strain of the larger women's health movement, exemplified these principles. The movement, founded in 1969 when Carol Downer demonstrated how women could see their own cervices using a mirror, a speculum, and a flashlight, promoted women's health. They toured nationally showing women how to see their interiors; they established self-help clinics where women gathered regularly to learn about their own and each others bodies; they published books and pamphlets based upon their own research; they established reproductive health clinics staffed largely with lay women; they campaigned in multiple venues (legislative, professional, and medical) to return control of women's bodies to women.

The gay and lesbian health movement emerged in the 1970s to combat "[the] hostility of mainstream health services and practitioners toward the issue of homosexuality in general and to homosexual men and women, in particular." Perhaps inspired by the successful 1973 campaign to remove homosexuality from the Diagnostic and Statistical Manual of Mental Disorders, gay and lesbians health care providers created professional organizations to increase gay visibility and to combat homophobia. The Gay Nurses' Alliance (1973) paved the way for other health professionals, including public health workers and pharmacists. In 1976, activists created the National Gay Health Coalition (later the National Coalition for LGBT Health) as an umbrella group, which became the "nexus of gay health activism." (Deyton, Bopper, Lear, Walter, 1988. A brief history of the gay/lesbian health movement in the U.S.A. In: Shernoff, Michael, Scott, William A. (Eds.), The Source Book on Lesbian/Gay Health Care, second ed. National Lesbian/Gay Health Foundation, Washington, D.C., pp. 15, 18.)

Activists, working at both the local and national levels, also attempted to meet the health needs of gay men, and to a lesser degree, lesbians, by establishing health clinics. As the human immunodeficiency virus infection/acquired immunodeficiency syndrome (HIV/AIDS) crisis began in 1981, much of the movement's attention focused on the epidemic and the critical health needs of gay men. Of the 11 gay and lesbian-focused clinics extant in 1992, 3 were founded in response to the AIDS epidemic; 2 others were founded as sexually transmitted disease (STD) clinics for gay men. (Untitled grant proposal, National Alliance of Lesbian and Gay Health Clinics, n.d. (1992).) Lesbians played important roles in the HIV/AIDS crisis, but it was often, although not exclusively, understood as work by lesbians for their gay male compatriots.

'Lesbian health' was formed within and emerged out of these larger social movements. Lesbians' health needs overlapped with women's health needs, and lesbians surely benefited from and participated in the efforts to combat sexism in medicine. Lesbians also contributed to efforts to combat homophobia in the health professions and to provide health care to gay men and lesbians. Neither women's health nor gay and lesbian health movements, however, put the health needs of lesbians first; lingering heterosexism and sexism helped foment a more targeted focus on lesbian health both within these movements and independent of them.

Creating Lesbian Health

Women's health issues brought to feminism many who had never before identified with the women's movement. Many of these new recruits were lesbians. In her history of the lesbian health movement, Risa Denenberg claims that many of the leaders of the women's health movement were lesbians. The proportion of lesbians in the movement seems to have varied significantly geographically. (Denenberg, Risa, 1997. A history of the lesbian health movement. In: White, Jocelyn, Martinez,

Marissa C. (Eds.), The Lesbian Health Book: Caring For Ourselves. Seal Press, Seattle.) Other women came to identify as lesbians after they became involved in the women's movement. Although many lesbians were involved in the women's health movement, lesbians frequently decried the alleged heterosexist, reproductive focus of the movement, and wondered what was in it for them. A lesbian from Iowa City explained the problem in 1975. In 'Is There Life After Abortions,' Freddy Brass lamented "do we have any energy left for ourselves after spending the day as a patient advocate for women getting abortions (or birth control or babies)? Do we even know what there is to be done for ourselves?" She understood the importance of securing reproductive services for all women, but she wanted to turn her attention to "… lesbian health care, lesbian health research, and how to acquire the technology to care for ourselves and do that research." This desire to focus on lesbian health encouraged Brass to leave the women's health movement. (Is There Life After Abortions? Lesbian Connection 1, 12 (November 1975). On concerns regarding the heterosexist nature of the self-help movement, see also Second Women-Controlled Women's Health Center Conference. Monthly Extract 3, 5 (December 1974/January 1975). For a similar critique, see I Am a Lesbian Health Care Worker, n.d. unpublished. Wayne State University, Walter P. Reuther Library, DFWHCC, Box 5, File 11: Lesbian Self-Help.) Lesbian health emerged from the critiques by Brass and others primarily as an unarticulated need that was neglected by the very movement dedicated to reconceiving women's health care. In this critique, lesbian health was separate from (and unmet by) women's health, and it therefore required and deserved its own particular focus. It was unclear from this critique, however, just what lesbian health might include.

Unlike Brass and others, some lesbians and straight health activists denied that the women's health movement was either heterosexist or homophobic, arguing instead that it ultimately benefited all women. In the oft-cited 1973 publication 'Lesbian Health Care,' Frances (Francie) Hornstein, a lesbian living in Iowa City, made the case. She was active in the Women's Liberation Front and hoped to transform her interest in women's health issues into feminist action. Her first efforts, bringing feminist sensibilities into "a local free clinic" were frustrated by the pervasive sexism even in this "alternative" setting. Still, she vowed to serve the health needs of women. When Carol Downer and Lorraine Rothman came to Iowa to demonstrate the 'Self-Help Clinic,' Hornstein witnessed "the most revolutionary concept in the area of women's health care." As she gained information and watched women learning from each other, she "saw very clearly just how we were going to create women's medicine!" In the aftermath of the demonstration, Hornstein and three of her Iowa City compatriots packed up and moved to Los Angeles to work with Downer and Rothman. (F[rances] Hornstein, 1973/1974. Lesbian Health Care. Feminist Women's Health Center, Los Angeles. pp. 1, 2.)

After arriving in Los Angeles, however, they began to hear grumblings from some lesbians, who asked, in effect, "Why would three nice lesbians like you want to work so hard for straight women?" Hornstein was shocked to hear the movement framed in such heterosexist terms. She condemned the lesbian critique as "foggy, irrational thinking." She countered: "The whole idea that we, as lesbians were being used by heterosexual women to do the work that would benefit only straight women was very narrow thinking…both in an immediate practical sense as well as in a wider political sense." Most importantly, however, she noted that abortion and contraception – the ability to control fertility – were "vital to all of us who are Feminists in light of the use of women's bodies by men for their purposes—from rape to population control—two issues that affect every one of us, regardless of our sexuality." Finally, she denied that reproductive health only affected straight women by reminding her readers that many lesbians have children and many others hope to. In sum, she insisted that "the myth that the women's health movement is for heterosexual women must be destroyed," because she believed that the movement's efforts to wrest control of women's bodies away from men benefited straight and lesbian women equally. For Hornstein, then, lesbian health was rightly and unambiguously a subset of women's health and thus addressed through the women's health movement. (Hornstein, Lesbian Health Care, 3.)

Many lesbians agreed with Hornstein and eagerly embraced the women's health movement, especially the self-help gynecology impulse that one claimed to be "…much like a course in self defense." "For as lesbians, we are the most likely to be intimidated, patronized, and literally ostracized by a male-dominated medical establishment which knows nothing—and cares even less—about the kinds of health care lesbians need and want." (Riley, Kathy, December 1974. Self-defense and health care. Lavender Woman 3, 5.) Other lesbians organized lesbians-only self-help events. In September 1976, for example, the Atlanta Lesbian Feminist Alliance held a potluck dinner and a self-help clinic. (Self-Help Clinic, ALFA Newsletter, September 1976, 6.) Lesbians in other cities (e.g., Berkeley and Chicago) created their own self-help groups. (Monthly Extract 5 (September/October 1976) and 2 (April/May 1973).) Presumably in response to demand, other health centers, many of them feminist, also held regular clinics devoted to meeting the health needs of well lesbians. (See, for example, 'Womyn's Night' every Tuesday at St. Marks Clinic, NYC sponsored by the Lesbian Health Collective. 'Lesbian Health Collective, St. Mark's Clinic', WomaNews, 1 (April 1980), 6. 'Lesbian Well-Woman Clinic', Feminist Women's Health Center, Atlanta, GA, n.d. Emma Goldman Clinic for Women in Iowa City also had monthly gynecology clinics for lesbians. Klein, Paula, 10 September 1980. Health Needs Assessment in a Lesbian Community. Emma Goldman Clinic (Iowa City, Iowa) records, Iowa Women's Archives, The University of Iowa Libraries, Iowa City, Box 14.)

These lesbian-centered clinics sometimes failed to attract crowds of enthusiastic or curious lesbians, however. The Emma Goldman Clinic for Women in Iowa City, for example, attempted to overcome the perception that the clinic had a heterosexual bias by sponsoring monthly gynecological clinics for lesbians, but lesbians failed to show up and the clinic ended. (Emma Goldman Clinic (Iowa City, Iowa) records, Iowa Women's Archives, The University of Iowa Libraries, Iowa City, Box 14, Minutes of Lesbian Health Committee. Minutes of 26 April 1976 meeting.)

The tensions around sexual identity within the women's health movement were also evident in *Our Bodies Ourselves* (*OBOS*). Probably because none of the original members of

the Boston Women's Health Book Collective identified as gay, lesbian's health needs (and sexuality) received short shrift in the original 1970 newsprint edition (*Women and Their Bodies*) and in the 1971 New England Free Press edition (*OBOS*). For the 1973 Simon and Schuster edition, the collective recruited women to write a chapter by and for lesbians, but *In Amerika They Call Us Dykes* suggests an unhappy collaboration. As the lesbian authors wrote: "We had no connection with the group that was writing the rest of the book … and in fact we disagreed, and still do, with many of their opinions." (Cited in Kline, *Bodies of Knowledge*, 37.) That the flagship women's health publication had to farm out its lesbian content to a separate organization challenges the claim that the women's health movement could fully meet the needs of lesbians. Over time, *OBOS* developed more lesbian-specific content and a critique of homophobia, but as of 1982, a lesbian reader still complained, "Only about 1/3 of the book applies to me." (Cited in Kline, *Bodies of Knowledge*, 38.)

By the mid-1970s, the lesbian feminist movement, separate from the lesbian health movement, had identified health issues that disproportionately affected the lesbian community. Homophobia and its relation to alcoholism was understood as a particular problem. In 1975, for example, the East Lansing, Michigan-based *Lesbian Connection* published a three-part series on 'Lesbians and Alcoholism.' These articles identified the "modern tragedy of lesbian alcoholism," claiming that one in seven lesbians was an alcoholic. 'Kristi,' the author of the articles blamed both homophobia, for condemning lesbians as "queers and perverts," and the gay bar scene, as the "only place where lesbians can be lesbians." In these articles, the author explained why lesbians might suffer disproportionately from alcoholism. "Not only are we oppressed by strait [sic] society, but we are also trapped by a subculture that condones drinking, and further ensnared by an institution that definitely encourages it." (Kristi, February 1975. Lesbians and alcoholism. Lesbian Connection 1, 4. See Kristi, March 1975. Lesbians and alcoholism: part II. Lesbian Connection 1, 6–8; see also Are you a lesbian alcoholic? Lesbian Connection 1, 18 (December 1974); and Catherine, May 1975. An address to alcoholic lesbians by a drunken Dyke. Lesbian Connection 1, 18–20.) These statements from the lesbian feminist movement highlight the possible health consequences of homophobia and demonstrate the need for a feminist critique of medical sexism to also be a critique of homophobia.

The women's health movement helped to create and define the category of lesbian health in a variety of ways. Emerging as a critique of the women's health movement, lesbian health was first identified as an absence, as a category of neglect, a symbol of the heterosexist assumptions of the women's health movement. In response, representatives of the women's health movement, both gay and straight, insisted that lesbians, because they were women, benefited from the movement's efforts to wrest control of women's bodies from men, constructing lesbian health as the beneficiary of the broader improvements in women's health created by the feminist health movement. Finally, health activists understood that lesbians might want to explore their bodies, sexuality, and health needs with other lesbians, so they established lesbian-centered events and clinics. In this way, the health movement constructed lesbian health as a category of service offered to lesbians. The larger women's health movement, however, did not place homophobia at the center of their critique of medicine. For the most part, that critique came from activists aligned with the lesbian feminist movement outside the parameters of the women's health movement.

Establishing Lesbian Health Institutions

Although some feminist health clinics offered lesbian nights and lesbian self-help clinics, these gestures were not enough for many lesbians. Uncomfortable with the homophobia of mainstream medicine and the heterosexism of some feminist alternatives, lesbians were more likely to skip routine health exams and to feel uncomfortable during health visits. In order to bring health care to underserved lesbians, a few lesbian feminists founded lesbian health clinics. These clinics provided an alternative to straight-focused women's clinics and to the male focused gay clinics that frequently treated lesbian health as an afterthought.

An early lesbian health clinic was developed in New York City. In 1974, Joan Waitkevicz and several other lesbian activists founded the St. Marks Women's Health Collective, which aimed to provide health care "by and for lesbians." Waitkevicz, a physician and a lesbian, was moved to offer lesbian-focused services because an acquaintance of hers had developed inoperable cervical cancer "because she didn't feel she could go to a regular doctor for a Pap test." (Labaton, Vivien, September/October 1998. Joan Waitkevicz: Putting Lesbian Health in Focus, Ms., 80.)

Another lesbian clinic was located in San Francisco. Lyon Martin Women's Health Services (named for early lesbian activists Del Martin and Phyllis Lyon) was conceived and founded by Patricia Robertson, a resident in obstetrics and gynecology; Sherron Mills, a nurse practitioner; and Alana Schilling, a medical administrator, all at the University of California San Francisco Medical School, to meet the needs of lesbians in San Francisco. When the clinic first opened in 1979, it was a small, makeshift production, operating two nights a week out of borrowed space with an all-volunteer staff. Every night the staff would cart in the patient charts, medical supplies, and educational materials to the clinic, and carry them away again at the end of the shift. The tenuous nature of the clinic, however, did not discourage clients. In 1980, working at full capacity, it served more than 500 patients. Believing that it could serve even more women with more space, the clinic opened its own offices in the Mission district in San Francisco in 1983.

After this move, many poor, monolingual Spanish-speaking women from the neighborhood, who were desperate to find a heath care facility that accepted Medi-Cal, claimed Lyon Martin as their own. As long as the majority of the clients remained lesbian identified, most of the clinic stakeholders were happy to serve any women in need of health care services. This take-all-comers philosophy was tested, however, when a new (1989) executive director, Marj Plumb, hoping to expand the clinic and expand it in a multicultural way, applied for and received funding for Lyon Martin to provide health and social services to HIV-infected women. While this expanded mission did bring in more women of color, many of whom desperately

needed quality health care, it diminished the percentage of women at the clinic who identified as lesbian. This led to a recurrent conflict about the mission and services of the clinic. Over the years since, various stakeholders – staff, clients, board members, funders, and community members – have debated the meaning of a 'lesbian health clinic.' Nevertheless, the clinic has thus far weathered these conflicts and continues (in 2013) to offer health care to the lesbian community of San Francisco.

When these clinics opened, they attracted patients because they offered a sensitive, experience-based alternative to the heterosexism so prevalent in the medical encounter. They could not however, claim special expertise in lesbian health issues since research on lesbian health barely existed in the 1970s. (Stevens, Patricia E., 1992. Lesbian health care research: a review of the literature from 1970–1990. Health Care for Women International 13, 91–120.)

Lesbians as a Topic of Health Research

Although it was accused of neglecting lesbian health needs, the women's health movement actually spearheaded efforts to research lesbian health concerns. Frances Hornstein's 1973 landmark piece 'Lesbian Health Care' focused on how venereal diseases and vaginal infections could be passed between women. Based on 2 years of feminist research at self-help clinics and with trusted medical professionals, Hornstein noted the rarity of STDs among lesbians but that some genital infections (e.g., warts and lice) might be passed between women.

Significantly for lesbian health, Hornstein admitted that not all women who identified as lesbians "relate sexually exclusively with women"; that some occasionally had sex with men, and that these women were at risk for the "serious health hazard[s]" of heterosexuality. This discussion highlights the slipperiness of the category of lesbian and how difficult it was to isolate lesbian health needs. Lesbians did experience venereal disease even if their status as lesbian might theoretically protect them from the perils of heterosexual sex. The lived experience of lesbians often included heterosexual practices. (Hornstein. Lesbian Health Care 4, 5.)

Other groups of activists quickly followed Hornstein with their own efforts to investigate and publicize the health needs of lesbians. (These groups included the Chico Feminist Women's Health Center; the Women's Community Health Center in Cambridge, Massachusetts; and the Emma Goldman Clinic for Women. Paula Klein and Suzanne Vilmain, Self-health for Lesbian Women, Emma Goldman Clinic for Women, 1978. Lesbian Self-help Group, Health Care for Lesbians, Chico Feminist Women's Health Center, n.d.; undated letter from Lesbian Pamphlet Group of the Women's Community Health Center to 'sisters'.) The most significant and comprehensive of these was the 1979 publication of *Lesbian Health Matters!* (1979) by the Santa Cruz Women's Health Collective. (For an overview of the state of lesbian health by mainstream and alternative publications see O'Donnell, Mary, 1978. Lesbian health care: issues and literature. Science for the People 10, 8–19.) *Lesbian Health Matters!* sought to consolidate health information specific to lesbians, provide information without heterosexist bias on various topics (e.g., menopause, alcoholism, self-care, and 'gynecological health'), educate providers about the health needs of lesbians, and build "strength and solidarity among lesbians." (O'Donnell, Mary, Pollock, Kater, Leoffler, Val, Saunders, Ziesel, 1979. Lesbian Health Matters! A Santa Cruz Women's Health Collective Publication, Santa Cruz. 5.) The pamphlet addressed issues of particular concern to lesbians including alternative fertilization and issues shared by straight and gay women (e.g., vaginitis). The book mixed the practical (avoid coffee while battling a bladder infection) with the political (lesbians use of alcohol to escape homophobia). In the end, the book identified the need for more research about lesbian health. The authors "suspect[ed]," for example, that certain health conditions were more common (breast cancer, alcoholism) or less common (syphilis, cervical cancer) in lesbians than in straight women, but they called for more research to provide "more accurate answers." (Lesbian Health Matters! 45.)

At the same time as the researching and publishing of *Lesbian Health Matters!*, other lesbians were also making lesbian health a research priority. These included a handful of lesbian physicians, psychologists, and medical students who were generally open at work and unafraid of the professional consequences of studying lesbians. (See, for example, Susan Johnson, an ob/gyn resident at the University of Iowa Medical School and Patricia Robertson, ob/gyn resident at University of California San Francisco Medical School.) These researchers did not see themselves as lesbian health activists; instead, they were meeting an unmet need of their community and advancing their professional careers. Nevertheless, these health care providers assumed significant risk in order to help identify the health status and health needs of lesbians.

By the 1980s, the medical literature on lesbian health, based almost exclusively on survey data, converged on several general claims: (1) lesbians frequently avoided medical professionals; (2) lesbians frequently withheld their lesbian identity from their health care providers; (3) many lesbians reported mistreatment from physicians after revealing their identity; (4) particular health risks or advantages of lesbians remained largely unstudied; and (5) the rates of alcoholism among lesbians appeared to be significantly higher (five to seven times higher) than in heterosexual women. These overarching findings demonstrated the need for further research into the health status of lesbians and the health consequences of homophobia. (See, for example, Johnson, Susan R., Guenther, Susan M., Laube, Douglas W., Keetel, William C., 1981. Factors influencing lesbian gynecologic care: a preliminary study. American Journal of Obstetrics and Gynecology 140, 20–28; Johnson, Susan R., Smith, Elaine M., Guenther, Susan M., 1987. Comparison of gynecologic health care problems between lesbians and bisexual women: a survey of 2345 women. The Journal of Reproductive Medicine 32, 805–811; Robertson, P., Schachter, J., 1981. Failure to identify venereal disease in a lesbian population. Sexually Transmitted Diseases 8, 75–76.)

Other survey research came out of a more explicitly activist impulse, often but not exclusively, supported by the fledgling gay and lesbian health movement. The most significant of these survey studies was the National Lesbian Health Care Survey (NLHCS) published in 1988. The idea for the NLHCS began in the late 1970s when activists in the nascent gay and lesbian

health movement noted the paucity of information on lesbian health. After securing sponsorship from the newly created National Gay Health Education Foundation – later known as the National Lesbian and Gay Health Foundation – and funding from the Msp Foundation, Caitlin Ryan, Bernice Goodman, and Judith Bradford set to work on an ambitious survey of lesbians across the country. The survey gathered and analyzed data from 1925 lesbians from every US state and several territories. This survey, published in 1988, remained the "most extensive study of lesbians" published through 2001. (Ryan, Caitlin, Bradford, Judith, 1999. Conducting the national lesbian health care survey: first of its kind. Journal of the Gay and Lesbian Medical Association 3, 91.)

This survey discovered and documented several things. Depression or sadness was the most common health problem; lesbians and straight women shared many health problems (e.g., arthritis, menstrual cramps, and allergies); nearly one-third of the lesbians had been pregnant and another third hoped to be; financial barriers kept many lesbians from getting the health care they needed; many lesbians resented the heterosexist attitude of their health care providers. In addition to these findings, the published report insisted that the real health status of lesbians would only improve through the broader social acceptance of lesbianism. It concluded: "unless service providers are able to view lesbianism as an acceptable lifestyle and not a symptom of mental illness or deviance, they risk delivering services that will be harmful rather than helpful or will prevent lesbians from accessing them." (Ryan, Caitlyn, Bradford, Judith, 1988. The National lesbian health care survey: an overview. In: Shernoff Michael, Scott, William A. (Eds.), The Sourcebook on Lesbian/Gay Health Care, second ed. National Lesbian/Gay Health Foundation, Washington, D.C., p. 39. See also Ryan, Caitlyn, Bradford, Judith, 1988. The National Lesbian Health Care Survey: Final Report. National Lesbian and Gay Health Fund.)

For most of the research in the 1970s and 1980s, the definition of 'lesbian' was generally unanalyzed. For the most part, lesbians qualified as lesbians for research purposes if they said they were. (Bisexuals, however they were defined, were sometimes considered in the same category as lesbians, sometimes in the category of straight women.) The research surveys were generally circulated through friend networks or distributed at various lesbian cultural sites including bars, musical festivals, and bookstores. Due to this method of data collection, the 'lesbian' studied was overwhelmingly white, middle class, and young. It captured those who identified with a cultural identity; it did not attempt to locate and survey those who participated in particular behaviors. Further, because cultural factors including race, ethnicity, and religion influence the acceptance of the label, using lesbian identity to recruit subjects probably underrepresented the women likely to have felt the effects of homophobia most intensely.

Building a Lesbian Health Movement

With the publication of the NLHCS, there was a flurry of activity on lesbian health matters. Grassroots lesbians were demanding more attention for their particular needs at gay community health centers. Gay civil rights groups included lesbian health as one of their concerns. (Warchafsky, Lynn, 1992. Lesbian Health Needs Assessment: Los Angeles, Los Angeles Gay and Lesbian Community Center; Michigan Organization for Human Rights, August 1991. Michigan Lesbian Health Survey, MOHR Special Report.) Lesbian health became the subject of books aimed at both medical and popular audiences. (See, for example, White, Jocelyn, Martinez, Marissa C., (Eds.), 1997. The Lesbian Health Book: Caring For Ourselves. Seal Press, Seattle; Stern, Phyllis Noerager (Ed.), 1993. Lesbian Health: What Are the Issues. Taylor and Francis, Washington, D.C.; Ponticelli, Christy M., 1995. Gateways to Improving Lesbian Health and Health Care: Opening Doors. Haworth Press, York.) Individual lesbians, touched by health issues, created foundations to address lesbian health issues. (Mautner Project for Lesbians with Cancer founded in 1989 is the most important of these private philanthropic ventures. In 2013, the Mautner project, which had abandoned its exclusive focus on cancer and had expanded its mission to include bisexual and transgender individuals, merged with Walker Whitman Health.) By the early 1990s, activists and observers considered these varied impulses a lesbian health movement. (See, for example, Denenberg, A History of the Women's Health Movement.)

One of the major milestones of this movement was attracting federal attention and dollars to the cause of lesbian health. In 1993, lesbian health activists met with Secretary of Health and Human Services Donna Shalala to request more federal attention to the health needs of LGBT individuals. In February 1994, lesbian and bisexual activists met in a Lesbian Health Roundtable to formalize recommendations to the DHHS and to establish a lesbian health agenda. (Solarz, Andrea L., (Ed.), 1999. Lesbian Health: Current Assessment and Directions for the Future. National Academy Press, Washington, D.C. IOM, viii.) These recommendations included the expansion of federally funded research on lesbian health issues. The Institutes of Medicine (IOM) took up this challenge, and in July 1997, it convened the Committee on Lesbian Health Research Priorities. The Committee was charged with assessing the extant research on the physical and mental health issues of lesbian, reviewing the methodological challenges involved in the research, and proposing a research agenda for the future. *Lesbian Health: Current Assessment and Directions for the Future* published in 1999 by the IOM was the path-breaking product of this workshop.

The IOM report highlighted the problems with the then-current research on lesbian health. The report, for example, cited research that demonstrated that lesbians have higher rates of some high-risk behaviors (e.g., smoking and problem drinking) and lower rates of some protective behaviors (e.g., pregnancy and oral contraceptive use) and thus claimed that lesbians were at increased risk (compared to women in general) of certain conditions including breast cancer and heart disease. The report cautioned, however, that no epidemiological evidence verified that lesbians truly suffered disproportionately from either breast cancer or heart disease. The report was willing to concede that lesbians, by virtue of having less heterosexual intercourse were "probably" at decreased risk for cervical cancer.

The report noted that the current reliance on survey data rather than on population data contributed to the current

uncertainty about the true health profile of lesbians. The report also pointed to the ambiguity in the category of lesbian itself. To illustrate the problem, the report cited a study that separated 'lesbian' into three possible characteristics: current same-sex desire, current identity as lesbian or bisexual, and same-sex behavior since age 18 years. The study showed that less than 16% of lesbians claimed all three aspects. This study highlighted the methodological incoherence plaguing the category 'lesbian' and called into question the legitimacy of comparing the extant literature on lesbian health.

Through questioning the existing literature, the existence of the IOM report fueled the visibility of the lesbian health movement and resulted in professional legitimacy for lesbian health research and other projects. In 1999, for example, the American Public Health Association called for more research on sexual orientation and gender identity. In June 2001, the *American Journal of Public Health* devoted its publication to LGBT public health. (Most, but not all, of the articles in this issue, however, lumped all the constituent populations of this acronym together, masking the unique aspects of lesbian health.) More researchers felt emboldened and inspired to undertake lesbian health research.

Some of this new research provided the population-based perspective called for in the IOM report. For example, a 2000 article published in the *Archives of Family Medicine* claimed to be the first study of lesbian health based on population data. The study confirmed earlier work that showed that lesbian and bisexual women were more likely than heterosexual women to have poor health behaviors (especially smoking and problem drinking), worse access to health care, and lower rates of satisfaction with their health care providers. (Diamant, Allison L., Wold, Cheryl, Spritzer, Karen, Gelberg, Lillian, 2000. Health behaviors, health status, and access to and use of health care: a population-based study of lesbian, bisexual, and heterosexual women. Archives of Family Medicine 9, 1043–1051.)

Who counted as a lesbian remained a problem in this new research. Population-based studies avoided some of the issues with survey data. It still often relied on self-identity as lesbian, however, and lesbian was increasingly recognized as a fuzzy category. In order to broaden the pool of research subjects, some researchers began calling for research on women who participated in same-sex sexual behaviors (women who have sex with women) rather than lesbians.

This new vocabulary and approach significantly expanded the breadth of the women whose interests were allegedly being served by the lesbian health agenda. It did not, however, clarify the scope of category of lesbian health. A review of the literature between 2000 and 2006 found that "sexual orientation was measured in more than 100 different ways" and that the results of the different classification schemes resulted in different understandings of the health consequences at play. (Bauer, Greta R., Jairam, Jennifer A., 2008. Are lesbians really women who have sex with women (WSW)? Methodological concerns in measuring sexual orientation in health research. Women and Health 48, 385.) Consequently, although the research on lesbian health increased, the ambiguity over who this category included remains unresolved.

The ambiguity over who counts as a lesbian in terms of research and access to health services has only become more obvious with the increasing number of lesbians who have come to identify as transgendered (or transsexual, transmen, Female-to-Male (FTM), *trans, or genderqueer). Over the last 20 or so years, transsexuals and transgender individuals have been an increasing visible and vocal part of the LGBT community. The health needs of transgender individuals are assuredly not identical to the needs of lesbians. Nevertheless, because many trans people emerge from the lesbian community and many remain identified with it, (Rafkin, Louise. Straddlng Sexes. SFGate.com (accessed 31.01.12.).) lesbian health concerns must now include the medical control of the embodied transition (testosterone use, surgery, surgical follow-up), as well as promoting respectful and sensitive general health care. Perhaps more importantly, the category of lesbian now includes people with varied embodied and psychological enactments of gender and sex. Looking out for the health needs of lesbians includes making sure that men with vaginas, women with penises, and lesbians who reject binary gender identities have a place to receive competent and compassionate health care without condescension or judgment. As trans-activist Leslie Feinberg put it, attention to the health needs of trans people "is life or death."

If the identity of the lesbian in lesbian health is and always has been unclear, the goals of the lesbian health movement have been and remain similarly uncertain. Health professionals clamor for more health research focused on lesbians. Lesbians of color demand a sustained analysis of the role of racism in the lesbian health movement and the health effects of racism on lesbian lives. Some lesbian health activists are committed to serving women with HIV/AIDS. Others focus on bringing reproductive technologies to lesbians. Homelessness, hunger, and poverty plague the lives of patients at lesbian clinics, but poverty has failed to emerge as a central concern of the lesbian health movement. By 2013, the movement has succeeded in gathering support and concern for lesbian health matters. It remains to be seen how the movement will decide which lesbians and which health matters matter most.

Abstract

At all times and in all cultures, attempts have been made and still are made, to cure diseases and alleviate suffering. In medicine in its narrow sense, the physician's appropriate action is derived from medico-scientific knowledge. Thus medicine developed as soon as diseases came to be explained 'according to nature' and were treated with scientific rationality. In the European context this took place in the fourth century BC in ancient Greece. We speak of 'medicine' and 'physician' only in contexts where diseases are not primarily seen in magical, mythical, religious, or purely empirical references. From ancient scientific beginnings in humoral pathology, different historical concepts of medicine have been generated via iatro-astrology, iatro-physics, iatro-chemistry, and iatro-morphology to the modern concept of iatro-technology. Concepts of medicine comprise a continuous causal interrelation between a particular physiology, a particular pathology, and its deducible therapy. This inner perspective of the scientific and conceptual history of Western medicine is broadened by an outer perspective. Guided by socio-historical, historico-sociological, and anthropological approaches, the institutional and organizational history of Western medicine is focused. In recent decades the leading concept of iatro-technological medicine is in transition to the molecular concept of medicine. The scientific medicine of the late nineteenth and early twentieth centuries was the reproductive rearguard of industrialization. By contrast, the medicine of the late twentieth and early twenty-first centuries is a forerunner of the ongoing scientific, economic, and social change. The transition to molecular medicine will reshape the concept of the human body and thus change individual life and the social world accordingly.

At all times and in all cultures attempts have been made to cure diseases and alleviate suffering. Healing methods nowadays range from experience-based medical treatment within the family and the lay-world to the theories and methods of experts. Medicine in a narrow sense refers to 'scientific' knowledge. Such special knowledge is distinct from other forms of knowledge following culturally characteristic criteria. The physician's appropriate action is derived from medico-scientific knowledge: We may only speak of 'medicine' and the 'physician' when diseases are not primarily seen in magical, mythical, religious, or empirical contexts. Medicine developed as soon as diseases came to be explained 'according to nature' and were treated with scientific rationality. Historically, this took place in the fourth century BC in ancient Greece. Scientific medicine generated subsequently from these ancient beginnings. This concept of modern Western medicine has come to be the leading concept of medicine world-wide. At the same time, there have always been alternative understandings and methods of medicine, which will also be mentioned briefly. Concepts of medicine comprise a continuous causal interrelation between a particular physiology, a particular pathology, and its deducible therapy. The inner perspective of the scientific and conceptual history of Western medicine (=1) will afterward be broadened by an outer perspective guided by *socio-historical*, *historico-sociological*, and *anthropological approaches* (=2). As we face a paradigmatic change of the concept of medicine in recent decades, the transition from the iatro-technological to the molecular concept of medicine will be analyzed profoundly (=3).

The Scientific and Conceptual History of Modern Western Medicine

The magical-mythical art of healing in indigenous cultures has been part of a world in which the human relationships both toward nature and toward societal structures have not been understood as independent in their own right. In a society of hunters and gatherers and in the early agriculturally determined cultures, diseases were the results of violated taboos, offended demons, or neglected ancestors. Therapies aimed at restoring the good old order: exorcism was practised, demons and ancestors were pacified and with this, the spiritual, physical, and social order were restored. The animistic-demonic medicine presented a closed rational system of thinking and acting. As the trepanations (perforations of the skull, which were disseminated world-wide) indicate, fairly complex surgical procedures were performed within this magical-mythical thinking.

Magical conceptions of the world not only had their effects on notions of disease and therapeutic methods of prescientific times but iatro-magic ('iatro' from ancient Greek '*iatros*': the physician) influenced medical theory and even practical medical action far into the seventeenth century AD. Even today, 'simile-magic' (e.g., ginseng-roots) or 'singularity-magic' (e.g., charms, symbols, spells) determine popular medicine, nature healing, and the so-called complementary medicine.

A religious world order characterized the highly developed medicine of the archaic cultures of Mesopotamia, Egypt, and Asia Minor. This order was guaranteed by (national) deities and the (divine) ruler. Diseases were seen as conscious or unconscious violations of the world order with which the healers were familiar. These healers were characterized by practical as well as prophetic skills. Thus physician and priest are hardly distinguishable. There was an abundance of empirical practices both in magical-mythical medicine and in the archaic art of healing. The one criterion that clearly distinguishes the latter from medicine in the narrow sense was that the entire art of healing remained metaphysically oriented. Even those treatments that worked also in the modern sense, were in their time assigned to a magical-mythical, i.e., religious domain. This also applied to rules of hygiene such as sanitary and dietary laws.

It was Hippocrates of Kos (*c*.460–375 BC) who took the decisive step toward scientific medicine in Classical Antiquity. Hippocrates and his school emancipated medicine from religious concepts. Diseases came to be explained 'according to nature.' Natural philosophical elements (fire, water, air, soil) and their qualities (warm, humid, cold, dry) were combined with the teachings of the body fluids (blood, phlegm, yellow and black bile) to become humoral pathology. Apart from this concept, ancient medicine developed in its progress a large spectrum of theories and methods in association with the respective philosophical schools. The spectrum ranged from the pathology of the body fluids (humoral pathology, humoralism) to the pathology of solid body parts (solid pathology). This included (functional) anatomy (including vivisections), surgery (e.g., vascular ligatures), and pharmacy (The Greek Herbal of Dioscorides Pedanius was written in the first century BC). The Alexandrine medical schools (Herophilus of Chalcedon, *c*.330–250 BC; and Erasistratus of Kos, *c*.320–245 BC) followed empirical, partly experimental concepts in the modern sense. With this, almost all the possible patterns of modern medical thinking were *in nuce* already put into practice, or at least, anticipated in Classical Antiquity.

Galen of Pergamum (AD 130–200) subsumed theory and practice of ancient medicine under a humoral pathological view. The authoritative Hippocratic–Galenian medicine entered Persian and Arabian medicine via Byzantium (e.g., Oribasius of Pergamum, *c*.325–400 BC, and Alexander of Tralles, *c*.525–600 BC). As a result of Islamization, Persian-Arabian medicine spread eastward to South East Asia and westward to the Iberian Peninsula. In the heyday of the Arabian-Islamic culture (AD seventh to twelfth centuries), ancient medicine was transformed into practice-oriented compendia in a process of independent scientific work. Far beyond the High Middle Ages, the 'Canon Medicinae' of Ibn Sina Avicenna (AD 980–1037) became the handbook even of Western European physicians.

For approximately 1500 years, humoralism was the dominating medical concept from India to Europe. The original theory of the four body fluids, qualities, and elements was constantly expanded: by the four temperaments (sanguine, phlegmatic, choleric, melancholic), by the four seasons, the 12 signs of the zodiac, then later by the four evangelists, certain musical scales etc. This concept allowed the physician to put the patient with his/her respective symptoms into the center of a comprehensive model: Continuously, the powers of the macrocosm and the microcosm mutually influenced each other within the individual. By means of thorough anamnesis, prognoses, and dietary instructions ('contraria contrariis'; allopathy) physicians supported the healing powers of nature ('vis medicatrix naturae'; 'medicus curat, natura sanat'), a model which (though according to the principle of 'similia similibus') is still valid today in homeopathy.

With the political decline of the Western Roman Empire during the fifth and sixth centuries, a Christian art of healing came to the fore in Western Europe. In this, the traditions of ancient practice (Cassiodor, AD 487–583) mingled with a magic-influenced popular art of healing and Christian cosmology to create the world of *Christus Medicus*. Such a theological-soteriological concept of medicine was able to take up the ancient cult of Asclepius. In early Christian and medieval 'iatro-theology,' diseases were interpreted as the result of sin or as a divine act of Providence. This still continues to have an effect on today's religious practices (votive tablets, intercessions, pilgrimages). In her medical writings (e.g., Physica; Causae et Curae), Hildegard of Bingen (AD 1098–1179) left abundant evidence of the medieval art of healing.

The so-called *monastic medicine* or *presalernitarian medicine* (AD sixth to twelfth centuries) was superseded in Southern Italy and Spain by the adoption of ancient traditions from Arabian medicine. With Salerno in the eleventh century (Constantinus Africanus, AD 1018–87) and Toledo in the twelfth century (Gerhard of Cremona, AD 1114–87 et al.), the era of scientifically oriented medicine taught at universities began (Northern Italy; Montpellier; Paris). Hippocratic–Galenian medicine became the all-embracing and generally binding concept.

Neoplatonism and astrology (e.g., Marsilius Ficino, 1433–99) contributed to shaping Hippocratic–Galenian medicine into an all-encompassing model of microcosm/macrocosm during the Renaissance. Though initially not directly critical of the authorities but of corrupted textual transmission, modern medicine has been gradually developing since the Renaissance. This development was furthered by numerous text discoveries (e.g., Celsus, approx. AD 40; De Re Medicina, discovered in AD 1455). *Andreas Vesal* (AD 1514–64) in his secular anatomical work 'De Humani Corporis Fabrica' (AD 1543) wanted to rid the old authorities of bad transmissions. More and more, medicine based itself on its own experience, on its own theories and on its own experiments ('experimenta ac ratio'). *Theophrast of Hohenheim*, known by the name of *Paracelsus* (AD 1493/94–1541) introduced a chemistry-oriented way of thinking into medicine, while René Descartes (AD 1596–1650) contributed a mathematical-mechanical thought pattern; both were complemented by *Francis Bacon's* (AD 1561–1626) empirical thinking. The human body was released from religious cosmology and gradually became the outstanding subject of scientific, i.e., (in the first place) anatomical examinations.

A secular step was taken at the end of the eighteenth and the beginning of nineteenth centuries in English and French hospitals: the focus of medicine and the physicians turned from the patient to his/her disease. The *sick man disappeared from medical cosmology*. Seventeenth century attempts at scientific systematization led to extensive nosologies (Thomas Sydenham, AD 1624–89) in medicine. The Hippocratic–Galenian symptomatology, which was directed at the individual patient, was replaced by described syndromes. These syndromes became detached from the individual sick person who turned into a mere case. With this, a scientific-experimental field of separate research of disease entities opened up for medicine.

The man–machine model of *iatro-physics* and the man–reagent model of *iatro-chemistry* finally introduced modern scientific thinking into medicine. As medicine was being progressively freed from any religious or metaphysical reasoning, the question of the source of life was raised. It was answered by dynamic concepts of disease, by psycho-dynamism and bio-dynamism. These concepts finally led, via Brownianism, to modern psychopathology and psychotherapy. In contrast, iatro-morphology was built on the visible and observable. Georgio Baglivi (AD 1668–1708) paved the way from humoral to solid pathology. Pathology improved from

Giovanni Battista Morgagni's (AD 1682–1771) organ pathology via *Francois-Xavier Bichat's* (AD 1771–1802) tissue pathology to the functional cellular pathology of *Rudolf Virchow* (AD 1821–1902). Cellular pathology established the physiological and pathological fundamentals of scientific medicine in a modern sense.

The actual step toward modern scientific medicine was taken in the late eighteenth and early nineteenth centuries. Initially chemical and physical, then biological thinking – which was gradually mathematically-statistically tested – has been determining the theories of medicine ever since. Deliberately reproducible (research) results led to a 'triumphal victory' of modern medicine in the second half of the nineteenth century. The development of anesthesia (nitric oxide AD 1844/46; AD 1846 ether; AD 1847 chloroform); antisepsis (Joseph Lister, AD 1827–1912); asepsis (AD 1886/1891: Ernst von Bergmann, AD 1836–1907; Curt Schimmelbusch, AD 1860–95); immunology; serum therapy; and the diagnostic (AD 1895/96) and therapeutic (AD 1896) possibilities of X-rays must be acknowledged for the surgical disciplines. With acetylsalicylic acid, the first chemically representable fever-reducing drug was introduced into medicine in 1873. Along with chemistry, industry with its economic concerns, became involved in medicine.

Modern scientific medicine follows the *iatro-technical concept*; pathophysiology, causal analysis of distinguishable disease entities, objectifying and gauging methods, and causal therapy characterize such medicine. The driving force of this scientifically and technically oriented medicine is its endeavor to put physiology, pathology, and therapy on a scientific footing; first chemistry, then physics became central guiding sciences; laboratories and experiments were introduced even into clinical practice. With the animal model, bacteriology launched a biological experimental situation. From the start, the *iatro-technical concept* created specific tensions in medicine: On the one hand, the scientific fundaments which aim at general insights get into the maelstrom of the physician's need for action (consequence: the 'autistic-indisciplined thinking' and acting; Eugen Bleuler, AD 1857–1915). On the other hand, medical action directed at the sick individual patient as a subject gets caught in the maelstrom of generalized technical applications and scientifically justifiable therapies (consequence: the '*therapeutic nihilism*' of the Second Viennese School; Josef Skoda, AD 1805–81). As a result, since the 1840s, both patients and medical practitioners have been turning to and from homeopathy and nature healing over and over again.

The Institutional and Organizational History of Western Medicine

Medicine is a science built neither on pure knowledge nor on mere empiricism. It is rather an 'action-based science' (Handlungswissenschaft), directed at the sick individual. As already formulated in Hippocrates' first aphorism, the patient and his/her environment are granted equal importance in medicine. Therefore, a scientific and conceptional internal perspective can only partly explain the significance of medicine. From a historical perspective, diachronic questions are necessary, directed at medicine from outside, i.e., from society. Consequently, a comprehensive history of medicine also demands socio-historical, historico-sociological and anthropological perspectives.

The dialectics of scientific knowledge and practical experience has been part of medicine ever since. Due to the category of experience, *history in medicine* has presented a significant argument since the existence of the earliest written evidence (such as: 'On Ancient Medicine' in the Corpus Hippocraticum). In the course of making medicine 'scientific' during the nineteenth century, the historical argument simply disappeared from scientific reasoning. As a well aimed counter-reaction against the purely scientific-technical concept, the history of medicine was reintroduced into the medical curriculum in the early twentieth century. Far into the 1990s, the history of medicine was considered in medical faculties and schools to be the substantial representative of the *humane aspects of medicine*. Just as much as objects and methods of the historical sciences began to expand in the late twentieth century, *medicine also became an object of general history*, i.e., especially of social and cultural history (*see* Social History; Environmental History; Body, History of; Gender History; etc.).

Similar to the steadily growing specialization of the scientific and clinical aspects of medicine, the sciences that specialized more and more dealt with the aspects of medical practice in the interaction of doctor and patient and the psychological and social environment of this interaction. Since the 1970s a broad canon of disciplines developed besides the classical history of medicine, so that a group of 'humanities in medicine' emerged. These can be summarized as: medical history, medical sociology, medical psychology, psychosomatic medicine as a special subject, economy of health care etc. With the increasing technical possibilities of modern medicine, especially at the beginning and the end of life, questions of an ethical nature got ever greater importance both in theory and in the clinic. Since the 1990s, the ethics of medicine has grown into its own as a theoretical and practical subject. Due to the different tasks to be addressed – which partly refer to the current problems of legitimization and action, and partly to the debate about contents and methods in historiography – it is useful to distinguish between a 'history of medicine' and a 'history in medicine.' 'History of medicine' can be conceived as a part of general history – 'history in medicine' is a part of the theory of medical action in its historic settings.

Within the doctor–patient encounter, patients receive special attention due to their special need for help, as do doctors due to their specific need for action. From Antiquity to the beginnings of scientific-technical medicine, the conceptual world of medicine and patients' lay interpretations have overlapped in large areas. Humoral pathological medicine lives on in popular medicine (Volksmedizin), in nature healing, and in alternative medicine ('rheumatism,' 'blood poisoning,' 'diets,' etc.). Due to the scientific concept, the world of medicine and that of the patient drifted apart. Since the eighteenth century, the physician as an expert began to face the patient as a lay person. At the same time, medicine came to hold the monopoly of definition and action over the human body. In the socio-genesis of health as a social good and value, medicine and the physicians were endowed with an exclusive task: They

were given a special position in the society. The historical and sociological discussion of the 1970s called this process 'the professionalization of medicine' (*see* Professions and Professionalization, History of).

The medical marketplace has always been characterized by enormous competition. Because of that, the healing professions have almost always depended on their clients, the patients. In medieval and early modern times, the patronage system made the academically trained physician subject to his socially superior patron–client. This was only inverted with the gradual scientification of medicine in the eighteenth century. With the compulsory linkage to scientific medicine, 'orthodox medicine (Schulmedizin)' has developed since the 1840s. Orthodox medicine was confronted with traditional or modern alternatives as a kind of 'outsider medicine'; healers who applied these methods were both internally and externally discriminated against as quack doctors. Industrial societies with their various forms of *social security systems* and their general claim of social inclusion, opened up for medicine a new clientele of the working class and the lower economic strata for medicine (*see* Poverty in History; Welfare State, History of; Social Inequality in History (Stratification and Classes)).

A significant institution of medical help both in the Western and in the Islamic tradition is the hospital: Hospitals (from Latin 'hospes,' meaning 'host') were established partly for pilgrims and partly for anybody in need of help, in order to fulfill the Christian ideal of 'caritas.' When it migrated to the orient along with ancient medicine, the hospital became the place of training for physicians in Islam, around the turn of the millennium. Within the European tradition, the charitably oriented hospital changed only in the late eighteenth century: The modern hospital (German: *Krankenhaus*) came to be a place to which only sick people were admitted, with the purpose of discharging them after a well-directed treatment within a calculable period of time. Such was initially the responsibility of proficient 'nursing.' Around the same time, selected hospitals had become places of practical training for future physicians. Scientific-medical research has also been conducted in these university hospitals from the 1840s onwards. Only as a result of antisepsis, medicine entered the General Hospitals in the 1860s. This was the beginning of the history of modern nursing, of scientifically oriented medical training, of the many medical disciplines, of the modern Medical Departments and Schools, and of the hospitals which only then became medically oriented.

On first sight, *diseases* embody the biological reality in the encounter between physician and patient. As the examples of leprosy or plagues show (*see* Plagues and Diseases in History), there are neither in one period nor over the periods, standardized terms to label diseases. Therefore it is hardly possible to determine with certainty which diseases were referred to in reports handed down to us (e.g., the so-called 'plague' of Thucydides). However, culturally interpreted diseases induce the encounter between physician and patient. It is therefore the sick human being who accounts for the existence of medicine. Over and above the conceptual and institutional interpretations, diseases have always been experienced as crises in human existence. In different cultures and eras sick people and their environments interpreted diseases always with reference to their metaphysical reasoning. Diseases are given a cultural meaning as a divine trial or as a retaliation for violated principles of life and nature. The scientific-analytical notion of disease in the iatro-technical concept is not suitable for taking the patient's quest for meaning into account. The chronically ill, the terminally ill, and the dying, therefore, present a constant challenge for scientific-technical medicine – including its necessarily inherent thoughts of progress. The result is a continuous push toward *alternative and complementary medicine as well as toward 'lay' and 'self' help*.

From an historical and sociological point of view, even the *interpretations of health* take place in a repetitive processes. In antiquity, health resulted from the philosophical ideal of the beautiful and good human being (ancient Greek: *'kalokagathia'*). The Islam and the Christian Middle Ages assigned the health of the body to religious categories. In the sciences of early modern times, the nature-bound human body came to be understood as an objectified body (The dichotomy of German: 'Leib/Körper' is a differentiation in philosophical anthropology which is hardly possible to translate into English: 'Leib' means the self-given presence of the body; 'Körper' means the scientifically perceived and shaped part of body as a 'living corpse'). In early rationalism, Gottfried Wilhelm Leibniz (AD 1646–1716) elevated medicine into a means of ordering private and public life according to scientific rules: the order of the soul, the order of the body, and the order of society corresponded with piety, health, and justice; they had to be guaranteed by the church, by medicine, and the judiciary. In critical rationalism, reason, physics, and morality were declared a unity (cp. Christoph Wilhelm Hufeland (AD 1762–1836), Macrobiotics). In the early nineteenth century, the interpretations of health joined the sciences. The question of the meaning of health was excluded from medicine. Within the iatro-technical concept, health as a chemical, physical, or statistical norm (percussion, auscultation, thermometer, etc.) became a negative definition of scientific notions of disease. Those values and ideas of order which were indispensably associated with the notion of health seem to have disappeared during the scientific-rational progress.

With the scientific notion of health and disease, modern medicine was finally granted the monopoly of interpretation and action for a rational design of the biological human resources in modern societies. Disease is the cause for medical action, health is its aim; via the societal value of health medical knowledge and medical action, it is integrated into the societal surroundings. The definition of health mediates in its valid interpretation of a particular civilization between the individual, the social, and the 'natural' nature of mankind. Thus, health integrates the 'natural' biological basis, the social basis, and the individuality – the 'I' and 'me' of human existence. *In terms of philosophical anthropology*, the valid notions of health mediate between the outer world/nature (= 'Aussenwelt'), the social world/society (= 'Mitwelt') and the inner world/individuality (= 'Innenwelt') with regard to their body/living corpse. The place and the scope of medical action in society are defined via the interpretation and the effect of the valid definitions of health.

To the same extent to which the human relationship toward nature becomes more scientific and leads to a scientific–technological civilization, more and more aspects become scientific within the combined interplay of the body as a part

of oneself ('Leib'), and the body as an object ('Körper'). The 'homo hygienicus,' i.e., mankind, who define themselves and are defined by others in terms of medical standards, are typical examples of the paradox of modernity: The autonomously progressing discoveries of scientifically oriented medicine liberated the person, the communities and society from the task of having to account for the values and norms of their bodily existence. From this position, the individual and public 'rationalization of the body,' as was stated by Max Weber (1864–1920), amongst others, at the turn of the century, could begin their widely welcomed and from all sides demanded 'victory march of medicine.' With the end of the belief in progress, the disadvantages of this process have been perceived since the 1970s. So in historical, sociological, and anthropological debates, medicine turned into an 'institution of social control.' '*Medicalization*' – as Michel Foucault (1926–84), amongst many others, pointed out from the early seventies onwards – became the focus of a fundamental critique on the penetrating social impact of modern medicine (*see* Body, History of; Gender History).

The doctor–patient relationship is no anthropological constant. Rather, this relationship is an integral part of the economic and social organization of a community. This is especially true for public medicine and the health sciences. Early forms of the modern public health service developed at the end of the thirteenth and the beginning of the fourteenth century, in North Italian cities. The driving forces were the endemic plagues, which kept coming back at regular intervals after the Great Plague of 1347–51 (*see* Plagues and Diseases in History). In early modern times those public health measures evolved and became regular institutions of the cities of commerce: General regulations which also had health effects (such as food inspection and market orders etc.); municipal supervision of those practicing medicine; city hospitals for the infirm, and others for special isolation (leprosaria, plague hospitals, etc.); the beginnings of the municipal doctor and surgeon service.

When the territorial states were thoroughly consolidated on the legal and administrative level, the medical and sanitary supervision unfolded in the late seventeenth and early eighteenth centuries. During Enlightened Absolutism, the 'medical police' (German: 'Medicinische Polizey'; e.g., Johann Peter Frank, 1745–1821) generated a public medicine which was linked to administrative and political goals. Within the framework of mercantilism, one intention in calculating power was to increase the population. The paternalistic welfare state toward the end of Absolutism developed 'public health' (German: Staatsarzneikunde) as part of its 'populating policy' (German: 'Peuplierungs-Politik'). This is where the special, still heavily disputed relationship between state, *medicine and women* (*see* Gender History) begins: to the extent to which women were made the 'human capital' of a well-directed population policy, their role came to be substantially determined by medicine (medicalised midwifery, medicalization of birth and childhood, medicalization of housekeeping, child-rearing, etc.)

Through the bourgeois revolutions the concept of the nation as sovereign made itself the object of public health. Besides the idea of a qualitative evaluation of the population the thought evolved to calculate 'the value of a human being in terms of money.' In a combined act of statistics, epidemiology, physics, geography, metereology, etc. and driven by a paternalistic idea of welfare, the first modern health sciences came into being. The nineteenth century cholera pandemics accelerated this development. With the beginning of industrialization, a comprehensive health care was promoted due to the recognition of the 'public value' of health. The modern health sciences finally defined, in a biological chain of causes and effects, a closed circle of human hygiene: the environment as conditional hygiene of Michel Levy (AD 1809–72), Jules Guérin (AD 1801–86), Edmund Parkes (AD 1819–76) or Max von Pettenkofer (AD 1818–1901); the concept of microbiology or bacteriology as infectious hygiene pioneered by Louis Pasteur (AD 1822–95) or Robert Koch (AD 1843–1910); the dynamic relation of exposition and disposition as constitutional hygiene; the classification of forthcoming human life through racial hygiene and eugenics; and finally the concept of health and society as social hygiene – all these combined approaches took hold of basically all areas of human existence in the late nineteenth and early twentieth centuries. This is especially true for the unborn life. At this point the historical reflection on public health care, medical statistics and epidemiology, health economics, health laws, and health systems etc. begins.

The idea of obligatory collective health has been developed since the turn of the twentieth century. In the *biologistic ideology of National Socialism* it was molded into a highly rational model of future-oriented health. The goal of *National Socialist health care* was a 'genetically healthy' and 'racially pure' population of 'Arian-German blood.' This genetically and racially cleansed 'Volk' would be fit to survive the secular 'war of races.' The goal of obligatory national – which really meant: racial – health was located beyond all individual rights. This model of a *totalitarian program of health care* was based categorically on exclusion. It was carried out in decisive areas: at first sterilization (at least 350 000 victims, all of them Germans), then 'euthanasia' (over 100 000 victims, including so-called 'wild euthanasia,' probably more than 250 000 victims; all of them Germans), and finally the determination of 'Völkerparasiten' during the Holocaust (approximately 6 million victims, approximately 180 000 Germans).

Medicine in National Socialism asks for special reference here, as it is historically unique in the world. Basically, there is always inherently an excluding function in medicine. In the daily routine of medicine this becomes apparent wherever decisions have to be made on scarce goods and services in short supply (e.g., transplantation medicine, assessment and social medicine, allocation of medical services). As to their forcefully carried out eugenic actions the National Socialists themselves referred to the examples of other countries, especially the United States. Indeed there had been, prior to 1933 and after 1945, an 'Internationale' of eugenicists. The National Socialist model of health serves as a historical example of the conflicting nature of the rationalization process on which modern times are based – a process which is irreversible. National Socialism is therefore to be seen as the janus-faced flipside of the modern era, which is just as much obsessed with progress as it is blinded by it. This means that National Socialism and medicine in the National Socialist era are not only a particular phenomena of German history. They are rather a problem of our times

and thereby a problem of all societies, which have built on modernism.

The Recent Transition to Molecular Medicine

In the 1980s the concept of a natural-scientific and iatrotechnological medicine began to shift into the concept of molecular medicine. The transition to molecular medicine has important implications for medicine and health care in general. A concept of medicine is a self-containing compound of a physiology, a pathology and a therapy. The concept of natural-scientific medicine and the consequent iatrotechnological approach – starting with Johannes Müller (AD 1801–58) and continued by his famous disciples such as Emil du Bois-Reymond (AD 1818–96), Hermann (of) Helmholtz (AD 1821–94), Rudolf Virchow (AD 1821–1902) or Ernst Haeckel (AD 1834–1919) – regarded the natural sciences as exclusive referential disciplines of modern medicine. Diseases appear to be incidents of a machinery that, in principle, can be repaired by chemical or physical, and technological interventions. From the 1980s and intensifying in the 1990s, the reference disciplines of chemistry and physics were replaced by biology, and especially by genetics. The necessary background technology is electronic data processing, which has accelerated research significantly, e.g., during the Human Genome Project, and in fact has even been the factor that made research possible in the first place. The classical natural sciences will not disappear, but they vanish into the second row, in order to clarify the novel issues raised by molecular genetics.

The transition to molecular medicine was – as always in such secular processes – accompanied by mistrust and misunderstanding. At the turn of the twenty-first century, even some doctors did not admit that a change was ongoing, at the same level of importance as the cellular pathology of Rudolf Virchow to medicine in the 1850s or the microbiology of Louis Pasteur and the bacteriology of Robert Koch to medicine in the 1870s and 1880s. In molecular medicine the cell is not the smallest explanatory unit, which can optionally be influenced chemically or physically or removed surgically or by strong radiation. The cell rather appears as a separate universe of significant data storage, messages, processes, products, and features. These highly complex events of the cell are controlled by a self-regulating process of genes (genomics), proteins (proteomics), and metabolism (metabolimics) that are in constant interchange with the requirements given from the outside (epi-genetics). Molecular biology and the genotype take the place of the former morphology and phenotype of features and processes. Two examples may illustrate this fundamental change. In molecular physiology mice lacking the gene for hemoglobin and thus lacking red blood cells, do not differ in their phenotype from mice that possess hemoglobin. Inflammation in rheumatoid arthritis has been previously treated with steroids and nonsteroidal, antiinflammatory drugs. The body is flooded with these drugs, in order to access the areas where the drugs must discharge their chemical effects. Of course, the drugs will work in many other areas, too. In molecular antirheumatic treatment the so-called biologicals are given. These drugs imitate human proteins and stop the destructive anti-autoimmune process. Thus, the disease is interrupted in its causal process. The intervention with TNF-alpha antagonists, however, is not specific to rheumatic arthritis, and therefore also can lead to serious side effects. This was noticed in the development of this therapy. As a result, rheumatologists have recently learned to treat the so-called 'nonresponders,' a group of patients particularly difficult to medicate.

Molecular medicine is the medicine that investigates biochemical processes from messages encoded in genes referring to the respective production processes up to the products of the cell – in particular nucleic acids and proteins – for the physiology and pathology of organisms, in order to use the results for an appropriate therapy. A person's genetic repertoire is a singular entity. Mankind is identified by its genes as individuals – today genetic fingerprints are customarily recognized in paternity or criminological studies (restriction enzymes, noncoding regions of DNA). Molecular medicine is a medicine that leads to an individualized, and personalized treatment. Ultimately drugs have to be prepared for the individual patient. This is already done in certain areas of medicine: for example, in hemat-oncology cytostatics are individually related to the specific surface marker of the individual patient. This explains the progress that has been achieved, particularly in children suffering from blood cancers.

The question that now arises is whether, when, and in what form molecular medicine gets relevance in health care and in society in general. All half-true, sensationalist, and imagined concerns against molecular medicine have to be excluded in advance. Cloning or genetic enhancement of humans are beyond biological possibility – if there should be some biological pathways, the results are unpredictable. These evil utopias reflect, however, the public fears and concern, which accompany this recent explosion of knowledge in medicine, just as it was in the case of cellular pathology in the 1850s or in bacteriology in the 1880s – impassioned conflicts that we have stored in (medical) history, and that we will similarly store in history in respect of molecular medicine, when it is taken for granted. These discussions are to be taken seriously, because they reveal a genetically transparent world. But these discussions also obscure the tasks arising from this new level of explanation of medicine. The connection to the classic discussions, especially of public health care, is obvious: wherever the genetic component of diseases seems to be known, since the development of eugenics in the 1880s, always a discussion arises about public interventions in medicine. Attached to molecular medicine are hopes and fears, which a society has to deal with openly. Individual rights, property rights on knowledge and ignorance, and the determination of the genetic self, sets the limits.

At this point individual and public medicine should be distinguished once more – on the one hand the individual and personal encounter between doctor and patient, on the other hand the public, mostly administrative, work of public medicine. Under the aspect of an anticipative health care – be it individual or public – molecular medicine reveals a new dimension. Risk assessments are carried out by statistical tests. These statistically calculated risks are always related to collectives, never to individuals. Molecular medicine differs insofar, as specific risks for a specified group of diseases can be clearly identified biologically – for example the recognition of the BRCA-1 or BRCA-2 genes as risks for developing breast

cancer. As a result, two new risk groups have to be differentiated. Those that do not have these genes are still a risk group for breast cancer. Those who carry the gene, represent a risk group with a biologically manifest, higher probability, (but not total) risk of developing this cancer. Those that carry these particular dangerous genes, have the possibility of preventing the disease risk resolutely. These preventive measures may be early surgery – such as in hereditary colon cancer (HNPCC, Lynch-Syndrome) or hereditary thyroid cancer (MEP2); a permanent monitoring, generally with BRCA; certain rules, for instance provision of increased protection against radiation in BRCA II; and upto a fatal waiting – as is the case of Huntington's disease. Generally, the new phenomenon of the 'healthy ill' emerges – the seemingly healthy patient who is exposed by hereditary features to an increased risk of disease and thus may have to live for decades facing this deleterious knowledge. This results in many other issues, such as the obligation to know and the right not to know at the individual level or risk-calculation in health or life insurances at a public level.

The task of a molecular medically oriented public health care would be to identify risk groups, to provide safe preventive measures, and to offer appropriate diagnosis and treatment if possible. This idea reveals the dilemma of a molecular, medically oriented, public health care. The basis of any effective public action of molecular medicine is a comprehensive genetic screening, or at least a systematic molecular epidemiology. The data should be stored in biobanks and made available to doctors and institutions of health care and the patient, respectively. Will this find public acceptance in view of the risk of data abuse, the possible violation of the right to personal data, and the chances of genetic identity leading to personal identifiability? Important for the consequences to organized medicine is the question of whether the data collected have, *a priori*, a clinical character. The collected data may directly lead to therapeutic interventions. This raises the question whether 'public health genetics' is a form of public health care or affiliated to curative medicine. A historic example is the transformation of the public mother and child care of the 1920s to individual peri-natal medicine since the 1960s. This raises the question of whether curative medicine has the perception and forms of public intervention. Public medicine can go out to vulnerable groups, while curative medicine is dependent on the demand of patients.

So on the one hand, there is the need to organize disease prevention, health promotion, and risk reduction based on molecular biological susceptibility to certain diseases. On the other hand, new forms of intervention are required for this new concept of public health genomics and protection, which unite the various areas of individualized medicine of gene testing, special interventions and preventive measures, to the necessary mass data and applied public health care measures. The facilities and measures that have been recently established, primarily take place at the level of research and the dissemination of available knowledge on international and national networks. Public interventions based on molecular medicine, such as in diabetology or in rheumatology, are as yet cohort studies or limited, research projects. Permanent forms of medical intervention of molecular public health care or of public health genetics have not yet been observed.

Conclusion and Outlook: Western Medicine and Molecular Health

In the narrow scientific-practical sense, medicine is determined by the dialectics of medical knowledge and medical action. Such dialectics have accompanied medicine since its first historical steps to its scientific-rational establishment in Greek Antiquity. So the controversy between 'dogmatists' and 'empiricists,' between 'medics' and 'doctors,' has characterized the positions during the entire history of medicine. It is the patient who gives these dialectics a direction: The patient's need for help constitutes medicine. Due to the patient and the special situation in which the patient and the doctor meet, medicine possesses a domain distinct from that of other sciences: In the encounter between doctor and patient medicine faces the necessity to take action. With this, the doctor–patient encounter is placed within a historical context. This is the starting point of historical reflection as an indispensable aspect, both of a 'history in medicine' and 'a history of medicine.'

In recent decades, mankind has experienced a fundamental change in all aspects of human life. During the eighteenth and nineteenth centuries the production of power shifted from humans and animals to machinery, with the then unforseeable consequences of industrialization. Today the production and distribution of data is being transferred from humans to machines, still with unpredictable consequences, (which finally will probably be even more dramatic than industrialization). Medicine is also covered by these processes. The position and the role of medicine within society is changing fundamentally. The scientific medicine of the late nineteenth and early twentieth centuries was the reproductive rearguard of industrialization. By contrast, the medicine of the late twentieth and early twenty-first centuries is a forerunner of scientific, economic, and social change. Since the 1980s, molecular biology has become the referential discipline of medicine. Thus it has become possible to diagnose diseases in their genetic informational principles and their molecular mechanisms. The molecular transition means a secular change in the concept of medicine. The molecular–biological thought pattern transfers the process of health and disease into the informational bases of the production and function of proteins. With that, genetics and information-processing in the cellular and extra-cellular realm, step into the limelight.

The historical analysis has shown to what extent medical knowledge and medical action affect society. Thus, experimental hygiene and bacteriology have cleansed and pasteurized conditions and behavior since the middle of the nineteenth century. Since the 1960s the pharmacological possibilities of contraception have altered the self-definition and the role of women fundamentally. Molecular genetics and clinical reproductive medicine already show their effects on the generative behavior of mankind (*in-vitro* and *in-vivo* fertilization, pre-implantation diagnostics etc.). The transition to molecular medicine will also change individual life and the social world: Molecular medicine leads to a new image of humans. The medicine of the last decades followed the model of 'exposition': diseases had an external origin (e.g., bacteria, viruses, stress factors, etc.). Molecular medicine shifts the etiology from exposition (i.e., the outside world of all human beings) to disposition and therefore to the (genetic) inner

world of the individual. Predispositions for certain diseases are internalized as an individual (biological) fate. The result is the 'genetization' of individual life and of its subsequent societal acts (e.g., life and health insurance). The interpretation of health including the notion of 'normality' of the body, will, in substance, be linked with knowledge of genetically determined dispositions. Such a genetic life world will be as 'real' for human beings of the coming decades as the bacteriological life world had been 'real' for the last century. The 'genetization of society' is the current aspect of the general 'medicalization' process and the continually progressing rationalization of corporeality.

Abstract

The Meiji Revolution between 1853 and 1877 saw the overthrow of Japan's military government by the Tokugawa shoguns presents and the restoration of the imperial rule of the Emperor. At the same time it has been seen as the rapid period of modernization in Japan and its entrance into the international scene as a modern commercial state. As such, the feudal state made up of *shogun* and *daimyo*, which had existed for more than 260 years, was destroyed, and it is in this sense that a genuine revolution can be identified. The revolution occurred in three stages: the first stage, the overthrow of the Bakufu (1853–68); the second stage, the restoration of Imperial Rule (1868–71); and the third stage, the centralized nation-state (1871–77).

Meiji is the era name adopted in 1868 by the new government that overthrew Japan's previous military government of the Tokugawa shoguns and readopted the emperor as the country's sovereign. Since 1853, when Matthew C. Perry, Commander of the American Squadron to the China Seas and Japan, first put military pressure on Japan to open up its borders to foreign commerce, the country had been quickly incorporated into the world's capitalist system. For the small feudal state that Japan had been up to that moment, the problem was to find a way to survive as an independent country and to decide on the type of state that would be able to deal with world capitalism and the international relations of East Asia. We shall call the great political and social changes that were the result of the political struggle, which developed around of this problem the Meiji Revolution. The political struggle can be divided into three stages: the first stage, the overthrow of the Bakufu (1853–68); the second stage, the restoration of Imperial Rule (1868–71); and the third stage, the centralized nation-state (1871–77). The political group, which took the leadership in the last stage, was the part of the samurai class that was in the process of being transformed into the bureaucracy of the new nation-state. We shall consider the year 1877, when the last rebellion of the samurai class was suppressed, the year of its completion.

The Meiji Revolution (1853–77)

Meiji ('Enlightened Government') is the era name adopted in 1868 by the new government that overthrew Japan's previous military government of the Tokugawa *shoguns* (*bakufu*) and readopted the emperor as the country's sovereign. Since 1853, when Matthew C. Perry, Commander of the American Squadron to the China Seas and Japan, first put military pressure on Japan to open up its borders to foreign intercourse, the country had been quickly incorporated into the world's capitalist system. For the small feudal state that Japan had been up to that moment, the problem was to find a way to survive as an independent country and to decide on the type of state that would be able to deal with world capitalism and the international relations of East Asia. The great political and social changes that were the result of the political struggle, which developed around this problem, we shall call here the Meiji Revolution. The year 1877, when the last rebellion of the samurai class was suppressed, we shall consider the year of its completion. The political struggle can be divided into three stages.

The First Stage: The Overthrow of the Bakufu (1853–68)

The *bakufu's* authority was greatly damaged by the fact that it had been forced to open up the country to intercourse with foreign powers. In order to stabilize its political foundation, the *bakufu* asked the *daimyo*, or feudal lords of Japan, for their opinions and groped toward achieving some kind of consensus among the *daimyo* class as a whole. On the other hand, it wanted to clarify the legitimacy of its own national government by strengthening its connection with the emperor in Kyoto, who nominally still was Japan's monarch. Moreover, the *bakufu* began to employ military drills in the Western-style and made a start to build its own navy tutored by naval officers from Holland. However, when the news that a joint English and French squadron, which had just defeated China in the Second Opium War was about to visit Japan in 1858, the *bakufu* buckled under this military pressure to sign treaties allowing free trade with the United States, Holland, Russia, England, and France. What is more, these treaties were unequal treaties in that they included clauses on extraterritoriality and fixed tariffs that denied Japan its legal and tax autonomy. The *bakufu* sought ratification of the treaties from Emperor Komei, but the emperor refused on the ground that Japan would cease to exist as an independent state if this attitude of acquiescence to the demands of the foreigners were to persist. As a result, the discussion about Japan's existence as a nation-state became divided between those supporting the *bakufu* and those backing the position of the emperor.

As a result of the opening, in 1859, of the harbors of Yokohama, Nagasaki, and Hakodate to free trade, Japan was quickly absorbed into the world's capitalist system. Prices rose precipitously, and the markets of the country were thrown into confusion. Voices denouncing the signing of the treaties and

the *bakufu*'s policy of submission to the foreigners arose not only among the members of the ruling class, but also among well-to-do farmers and merchants, and so became a protest of the Japanese people as a whole. As a result, the *bakufu* lost confidence in its ability to rule the country. By contrast, the idea of a government that would take a hard line toward the foreigners and make the *bakufu* cooperate with that effort was gaining in popularity among those supporting Emperor Komei, who continued to refuse to ratify the treaties. Powerful *daimyo*, who, in their turn, were thinking of taking up the right to govern the country themselves, were also found supporting this idea.

Warriors of the faction that proposed radical military reforms wanted to throw out the foreigners even more badly. They were of the opinion that there was no military advantage to be gained just by superficially adopting Western-style drilling methods, while keeping the old feudal system linking military ranks with family background. They stressed that Japan should aim to modernize its army while engaged in actual battle and so they wanted to use war to accomplish internal reform. Thus, in June of 1863, radicals from the domain of Choshu first attacked foreign shipping in the Straits of Shimonoseki in order to force the shogun to take military action against the foreigners, for the country's leadership in such matters was considered to be his responsibility. However, this type of behavior by the radical warriors, which showed no regard for the feudal order, frightened Emperor Komei and the highest officials of his court. They proceeded, in September of 1863, to chase the Choshu warriors from Kyoto with the help of the warriors from the Aizu domain in northeastern Japan, which traditionally supported the *bakufu*.

On the other hand, the Great Powers of Europe and the United States, which had concluded treaties with Japan, would not allow a native movement that aimed to break away from world capitalism by military force. Therefore, they decided to complete Japan's incorporation into the world's capitalist system by dealing its radical faction some harsh blows. In August of 1863, an English naval squadron attacked the home base of the Satsuma at Kagoshima. Next, in September of 1864, a joint naval force of English, French, American, and Dutch warships attacked the strategic port of Shimonoseki in Choshu. This fief had been declared an 'Enemy of the Imperial Court' by Emperor Komei, because its soldiers had entered the capital against his will. Moreover, in November of 1865, the joint naval force of these four nations penetrated Osaka Bay, and obtained from Emperor Komei, through military pressure, the ratification of the treaties. Thus, Satsuma and Choshu both painfully experienced Western military power at first hand. They were, therefore, also the first to understand that, in order to resist foreign pressure, it would be necessary to bundle the power of the entire Japanese people through the establishment of a unified nation-state. They became convinced that, as a first step to accomplish this, they should take immediate and drastic measures to reform their military forces.

In Satsuma, the old system based on lineage was abandoned and a new homogeneous army of samurai warriors established. In Choshu, lower ranking samurai, farmers, and townsmen joined to form an armed militia or *shotai*. The *bakufu*, on the other hand, used the opportunity offered by the fact that Choshu had been named an 'Enemy of the Imperial Court' and the domain's defeat at Shimonoseki to try and reestablish its authority. It succeeded in co-opting the Court and in destroying the lateral alliance of the powerful *daimyo*. In 1866, with the sanction of the Emperor, the *bakufu* organized an expedition to punish Choshu, but the domain had just concluded a military alliance with Satsuma and with its newly organized militia it was able to defeat the army of the *bakufu*.

The Second Stage: The Restoration of Imperial Rule (1868–71)

In a *coup d'etat* of January 1868, samurai from Satsuma, convinced that it would be impossible to establish a strong nation-state under the leadership of the Tokugawa, together with Tosa warriors and members of the Imperial Court, who were concerned with the loss of prestige the Imperial House had suffered because of its recent connection with the *bakufu*, took over power and established a government based on the restoration of imperial rule (*osei fukko*). Warriors from Satsuma, Choshu (which had obtained a cancellation of the order declaring it to be an 'Enemy of the Imperial Court'), and Tosa defeated the *bakufu*'s forces near Kyoto in the same month. By means of a civil war, which continued until June of 1869, the restoration government was able, with the cooperation from the domains, to eradicate the power of the old *bakufu* and to seize the lands, which had been under its jurisdiction. The Tokugawa family was reduced to nothing more than being one of many *daimyo*. The restoration government made Emperor Meiji, who had been born in 1852 and had succeeded to the throne after the death of his father Komei in 1866, the country's new sovereign. Instead of the slogan *Sonno joi* ('Revere the Emperor and Expel the Barbarian') through which it had come to power, the new government now stressed Japan's national power with a new slogan *Bankoku Taiji* ('Holding Out Against All Nations of the World'). Also, in order to obtain support for the new government, the new leaders criticized the autocratic nature of the old *bakufu*, professed its respect for public opinion, and established a deliberative assembly the members of which were elected by the domains.

During the one-and-a-half-year long civil war, which claimed more than 10 000 lives, the idea that birth should determine social standing was abandoned in the domains of the various *daimyo*, which also Westernized their military forces and accepted the participation of rich farmers and merchants in their local governments. For these men, it was natural to expect that the army of the new Japanese nation-state would consist of the combined military forces of the domains. But to the restoration government, it seemed that trying to take a hard line against the foreign powers in this manner might spiral the power of the local samurai out of control. Conversely, the leaders of the domains attacked the weakness of the government's foreign policy. The effort to stabilize a hard-line government based on a consensus and with the cooperation of the domains was abandoned. In August of 1871, after several 1000 elite warriors from the three domains of Satsuma, Choshu, and Tosa, had gathered in Tokyo, the government took the drastic measure of abolishing the domains and establishing prefectures, saying that "The existence of the domains hurts the realization of the *Bankoku Taiji* policy,"

The Third Stage: The Centralized Nation-State (1871–77)

Therefore, the problem of establishing this was felt to be an urgent matter to be accomplished through the cooperation of the three domains mentioned above. These, together with the domain of Hizen, formed the backbone of the new government. In December of the same year, Iwakura Tomomi (the Court), Okubo Toshimichi (Satsuma), and Kido Koin (Choshu) and others were sent as the representatives of the new government on an embassy to the United States and Europe in order to revise the unequal treaties. Saigo Takamori (Satsuma) was the most important man of the caretaker government remaining behind in Japan and he forcefully pursued the legal and institutional reforms that would make the Great Powers agree to a revision of the treaties. In order to accomplish this, the armament factories and the ships built and owned for the sake of modernization by the *bakufu* and the different domains were brought under government control, students were sent overseas, and many able foreigners were employed. Ten percent of the original assessed income of their former domain was given as personal property to the *daimyo*, and the courtiers (even those of the lowest ranks) were assured an income at the same level as the former *daimyo*. The government, however, aimed at building a nation-state on the model of those in Europe and America, which required an enormous outlay of funds. For this reason it did not relieve the tax burden required of the farmers. Also, there was no agreement between the four domains on the question of how to deal with the warrior class. Even though their stipends had been guaranteed, from 1873 an army draft had been started from among all layers of the population in order to be able to suppress internal rebellions. Therefore, it became necessary to face the problem of the position of the samurai in the new society.

When the caretaker government in Japan realized that, is the short term, a revision of the treaties was out of the question, it strengthened its intention to display the energy and prestige of the new Japanese nation-state within East Asia. The Japanese government wanted to assure its prestige in an East Asian world that seemed dominated by continuing concessions to the Great Powers of Europe and the United States since the defeat of the Qing in 1842. It hoped in this way to heighten the prestige of the new nation-state at home and decided it could use the samurai class to project its military power. Already in 1871, during negotiations with the Qing the Japanese had started to build new international relationships in East Asia. When aborigines from Taiwan harmed and killed some inhabitants of the Ryukyu Islands, which traditionally paid tribute to both China and Japan, this was used as an excuse to plan a military expedition to Taiwan. Moreover, the government considered the attitude of Korea, which had refused, since 1868, to negotiate with Japan because its diplomatic form was no longer that used by the Tokugawa *bakufu*, an affront to its national prestige. For this reason, in August of 1873, the caretaker government decided to send an embassy with the message that it was ready to go to war over this issue. However, the chief ambassador of the delegation that had been sent to Europe and the United States, Iwakura, came back to Japan in September of that year and forcefully opposed this idea. He was supported by that part of the samurai class that was in the process of being transformed into the bureaucracy of the new nation-state.

Because Emperor Meiji canceled the decision to send the embassy, Saigo and Eto Shinpei (Hizen), who had been the main members of the caretaker government, resigned from the government. The Satsuma and Tosa warriors, who were living in Tokyo as part of the Imperial Household guards, seceded from this force, and in February of 1874, the samurai of Hizen rebelled under the leadership of Eto. The Meiji government, now mainly led by Iwakura and Okubo, used the warships it had collected and the newly installed nationwide telegraph network to the maximum extent possible and subdued the insurrection within a short time, thus preventing it from spreading. However, in order to win over the armed forces and its officer corps, which both still mainly consisted of samurai, the government proceeded with the invasion of Taiwan in April 1874. Ignoring China's protest that this was an infringement of its national sovereignty and showing its readiness to go to war with the Qing, the government showed that it was able to take a hard line. When the Qing recognized, at the very last moment in October 1874, that the Taiwan expedition had been a 'heroic act,' the Japanese leadership learned it need not respect the power of the Qing. On the other hand, from the attitude China had taken on the Taiwan issue, it was possible to forecast that, in case of a Japanese dispute with Korea, the Qing, even though it was officially Korea's suzerain, would not come to its rescue. Moreover, it was becoming clear that if Japan engaged in military ventures in East Asia the Western powers were likely to remain neutral.

On the national level, this success earned the government the loyalty of its officer corps and, across the board, the pace toward a system of general conscription was accelerated in order to prepare for war. For the first time, it seemed possible to replace the samurai class and establish bureaucratic control over the army. In February 1876, Japan imposed, through military force, an unequal treaty on Korea, which had kept itself isolated in a manner similar to Japan before Perry's arrival. Also, with the treaty concluded with Russia in May 1875, by which Sachalin was exchanged for the Kuril islands, the government succeeded in solving a border dispute, which had existed since the last years of the eighteenth century.

So between 1874 and 1876, the Meiji government gave permanent shape to Japan's borders and reorganized its international relations with East Asia. In this way, it put an end to the general feeling among the population of Japan, existing since the 1840s, that the state was in a crisis which might lead to its dissolution. The only problem left was the revision of the unequal treaties with the Great Powers of Europe and the United States.

With the national prestige the government harvested from these developments, it decided to embark on some radical internal reforms. These reforms were meant to create the conditions necessary to establish capitalism in Japan, which, in turn, would enable the country to respond adequately to world capitalism. One of these conditions was to revise the land tax and to establish the right to private ownership of land without diminishing the national tax income as a whole, and the government meant to accomplish this within 1876. Another was to convert the stipends of the former *daimyo*, the courtiers, and the samurai into government bonds

(August 1876). This latter reform was no rejection of feudalism, but rather a decision to change it into a tool for the adoption of capitalism.

The land tax reform called forth a movement that opposed the fixation of the taxes at the high levels of feudalism. This opposition was led by rich farmers, and peasant rebellions exploded, one after another, in virtually all regions of Japan. At the same time, from October 1876, a revolt by samurai broke out that reached its peak with the Satsuma rebellion of February 1877. In January of that year, therefore, the government lowered the land tax from 3% to 2.5% of the land value and also diminished the local taxes. This drove a wedge between the peasant movement and the samurai rebellion and allowed the government, after a violent struggle lasting 8 months, to defeat, with its conscription army of 60 000 men, the 40 000 samurai of Satsuma. As a result, the movement to incorporate the samurai class into the structure of the nation-state was extinguished and the power of the new state was no longer challenged.

However, after its defeat, the samurai class held the government to its original promise to respect public opinion and it became the foremost power in the struggle for the opening of the National Diet to all classes of Japanese society. In this struggle, the samurai, allied with the rich farmers and merchants who stressed that there could be no taxation without representation, opposed the increasingly authoritarian Meiji government. And so the struggle, which had centered on the manner in which national power was to be wielded, now transformed itself into one for democratic rights for everyone.

Historiography of the Meiji Revolution

These events were, until the second decade of the twentieth century, considered to be the epochal restoration of direct imperial rule, accomplished by the imperial house with the reverent support of the Japanese people. When Japanese capitalism reached a dead end during the 1920s, with its repressive system at home and its increasingly aggressive policies abroad, Japanese social scientists, and Marxists, in particular, started to link the unholy trinity of monopoly capital dominating the country's political system, its half-feudal land ownership, and its imperially indoctrinated army and bureaucratic leadership with these events that were now known as the Meiji Restoration. This train of thought divided itself into two schools, one maintaining that the Meiji Restoration was an incomplete bourgeois revolution and the other that it was nothing but the establishment of absolutism. After World War II, and especially during the 1960s, the prewar interpretations were considered to be flawed because they neglected the concrete facts of the international situation around Japan at the time of the revolution and had been narrowly focused on the events as one stage in the development of the Japanese nation by itself. According to this thinking, foreign pressure in the middle of the nineteenth century forced the realization that if Japan wanted to keep its independence, it needed to cooperate in achieving a thorough overhaul of the state. Because a bourgeois revolution was not necessarily an indispensable ingredient for the success of the capitalist system transplanted to Japan in the second half of the nineteenth century, the revolution compromised and merged with the feudal elements of Japanese society.

However, today the positions are divided as follows. One group of historians stresses the fact that the transition to modern society was comparatively easy because of the high levels of social and economic development in Japanese society during the second half of the Edo period (1600–1867). Another group of historians considers the Meiji Restoration a popular or a nationalist revolution, ignoring such problems as feudalism, class, and the status of power holders. While recognizing a certain level of development in premodern Japan, a third group maintains that the Meiji Restoration was the formation of a centralized imperial state, which aimed to establish capitalism on a basis of support for the old nobility and the *daimyo* class of Tokugawa society. During this process of introducing world capitalism into Japan, the state itself went through several transformations.

Issues of the Debate on the Meiji Revolution

The Meiji Revolution presents, by its very nature, a complicated problem. On the one hand, it should be called a 'restoration of imperial rule' because of the efforts that were made to revive the structure of the imperial state that had centralized power in Japan more than 1200 years earlier. Until 1945, the position of the emperor as the supreme wielder of power in the modern Japanese state seemed to be fixed, and this in itself continued to confront and suppress all political thought stressing the sovereignty of the Japanese people. On the other hand, in the sense that the feudal state made up of *shogun* and *daimyo*, which had existed for more than 260 years, was destroyed, it can be called a sort of revolution. This Asian-style nation-state, which had existed since the beginning of the seventeenth century, could not have gradually reorganized and modernized itself from above without the overwhelming military and economic pressures from world capitalism of the second half of the nineteenth century.

In Japan, the men responsible for these revolutionary changes did not come from the bourgeoisie as in the case of Western-style revolutions. During Japan's closed country policy, a new class of rich farmers and merchants had, to a certain degree, emerged with the formation of a national market that involved the whole country, but not the outside world. Their nationalism formed the basis of and fueled the changes that took place. However, the leaders of the Meiji period were a group of men, who had their roots in the warrior class and had changed themselves into a literary and military bureaucracy while treating the state as their private property. By 1877, they had gained complete control of the Japanese state with the emperor at its head. However, without the support of the rich farmers, merchants, and ex-samurai, political and social stability still eluded them. This had to wait until the 1890s, when a constitution had been put in place and a parliament was established so that other groups might have some say in the running of the government. In the very broadest sense, Japan's Meiji Revolution ranks with Germany, Italy, and Russia as one of the latecomers in the drive toward modernization. Further generalizing seems to be meaningless, and this author would like to stress that the revolution creating

a nation-state in response to foreign pressure was probably the result of the specific circumstances existing in the second half of the nineteenth century in East Asia.

Meltzoff's "Like Me" Theory

Daina Crafa, Douglas Mental Health Institute, McGill University, Montreal, QC, Canada

Abstract

The 'Like Me' theory, proposed by American psychologist Andrew Meltzoff, suggests that infants understand the behaviors of others through their own body movements. This process, called self–other mapping, allows infants to learn new actions and to interpret the intentions of others. This system of representation appears to be innate and has implications for human social development and empathy as well as related neural processes, such as mirror neurons, and disorders, such as autism.

Theoretical Background

The 'Like Me' theory was proposed by contemporary American psychologist Andrew Meltzoff as a description of human social learning. This theory was developed based on a series of experiments, which demonstrated that infants represent the actions of others as analogous to their own actions. These experiments also show that infants assume these analogous actions accompanied by analogous psychological states, including similar perceptions, emotions, and intentions (Meltzoff, 2007a).

The 'Like Me' theory suggests that the actions of others are cross-modally mapped onto the infants' own bodily movements (Meltzoff, 2007b), meaning that when the actions of others are observed they are represented to the infant through the infants' *body schema* (Gallagher and Meltzoff, 1996). According to the 'Like Me' theory, this process, which is commonly termed *self–other mapping*, acts as the foundation for interpreting others. Through self–other mapping of actions, accompanying psychological states are also consequently mapped. Through mapping the actions and psychological states of others onto oneself, the infant gains access to interpreting these actions and states (Meltzoff, 2007b).

The interpretation of these actions and states are considered to be *supramodal*, meaning that the observation and execution of actions share a common framework. In other words, mapping the actions of the other onto the body schema of the self gives the infant the ability not only to interpret these actions but also to execute them. To put this idea even more simply, self–other mapping gives the infant the ability to simultaneously interpret and imitate the actions of others. Through these abilities, infants understand other people as being like themselves.

This 'Like Me' understanding of others is theorized to give rise to more complex processes, such as social learning and empathy. For example, as earlier research by Meltzoff (1995) demonstrates, children as young as 18 months old are able to infer an adult's intended actions by watching them make failed attempts. After viewing failed attempts, children were observed pursuing the intended goal by taking other actions rather than imitating the adult's mistakes. In contrast, when adults successfully accomplished their intended goal, the children imitated the observed actions. Observation combined with the 'Like Me' understanding of others essentially allows infants to learn possible outcomes and consequences of their own actions by watching others.

Such findings support one of the central claims of the 'Like Me' theory: that cross-modal mapping of the action of others drives child development and social learning, at least in part. Through social observation, children can use a combination of action imitation and modification to pursue successful achievement of the intentions of others (and presumably also of themselves). Invocation of the intentions of others is thought to be an early reflection of the human drive to compete and is proposed as propelling human development by motivating the acquisition of new skills (Meltzoff, 2007a).

Meltzoff proposes that the 'Like Me' framework is already present the first day of life, corresponding with the first observed imitative acts (Meltzoff and Moore, 1977). Given its early emergence in neonates and subsequent ability to drive development, this framework is proposed as "the starting point for social cognition, not its culmination" (Meltzoff, 2007a: p. 126).

Experimental Background

Early Experiments

In the 1970s to the 1980s, the early experimental predecessors of the 'Like Me' theory focused on infant imitation during the first hours and months of life. Perhaps the most famous of these experiments is a 1977 study that Meltzoff and Moore published in *Science*, in which they showed still images of infants imitating the facial expressions of adult researchers (see **Figure 1**). In this experiment, infants aged 12–21 days saw a researcher displaying three randomly ordered facial expressions: tongue protrusion, open mouth, and lip protrusion. Infants were observed imitating the modeled behaviors, and it was then theorized that infants could model gestures supramodally. A second study by Meltzoff and Moore, published in 1983, corroborated these findings by demonstrating that infants as young as 0.7–71 h old could imitate tongue protrusion and mouth opening. The early age of these behaviors rule out possibilities that they were actions previously learned at home, and support the thesis that infants are born with the innate ability to represent and imitate the visual actions of others. This research ultimately provides a historical and theoretical foundation for the 'Like Me' theory.

Testing the 'Like Me' Theory

The 'Like Me' theory was tested from three different angles, each building on top of its predecessor (Meltzoff, 2007a). First, it was tested whether infants perceived the *actions* of others as

Figure 1 Still images of infants imitating an adult experimenter, originally published in Meltzoff and Moore, 1977. Imitation of facial and manual gestures by human neonates. Science 198, 75. (Reprinted with permission.)

equivalent to their own. Second, it was tested whether infants perceived the *perceptions* of others as equivalent to their own. Third, it was tested whether infants perceived the *actions* of others as *relevant to or informative* for their own.

Acts 'Like Me'

In the first experiment, 14-month-old infants were placed across from two adults. The two adults mimicked the infants' behaviors, either in real time or with a short delay. This created the appearance that one adult was copying the infant's behaviors, while the second adult appeared to be performing similar behaviors to the infant but not identical. Infants' behaviors were evaluated to see which adult they preferred, based on who they looked at longer and smiled at more. In line with the initial hypotheses, this study demonstrated that infants preferred the researcher who acted the most like themselves. These findings were interpreted as demonstrating that the infants have an awareness of their own actions and actions that are 'Like Me.' Implicitly, this suggests that they have a system for representation the actions of another person enough to discriminate between similar and dissimilar actions. It also demonstrates that these action representations are temporally locked to the initial actions.

Perceives 'Like Me'

In the second experiment, it was tested whether infants understood that another person needed to have an unobstructed line of sight in order to see something. To test this, infants watched an adult turn his or her head while having the eyes either open or closed. The head movements corresponded with an object movement. Infants were tested to see whether they looked or pointed at the adult or followed the adult's gaze to the object. Infants looked longer at the object and pointed more often when the adult's eyes were open. As a follow-up experiment, infants were given time to play with the blindfold or headband, and some infants were briefly blindfolded with either a normal blindfold or one that had a window cut out so that they could still see. Then, adults wore either a blindfold or a headband in their respective normal fashions and moved their head in the direction of an object. Infants who had previous experience with an opaque blindfold showed different behaviors compared to those who had not. This study demonstrated that infants who had their vision obscured by a blindfold understood that the adults wearing a blindfold could not see. Together, these two experiments show that the 'Like Me' framework is developed through experience with the external world and that the perception of others are compared to these past experiences through the 'Like Me' analogy.

Experiences 'Like Me'

In the third experiment, infants were situated so that they could eavesdrop on an interaction between two adults. One adult was given an object to manipulate, while the second adult would either respond neutrally or angrily when the first did. Later, infants were given the same object – and sometimes the second adult was looking at them during this manipulation, while other times they had their backs turned. Infants were significantly more likely to manipulate the object if the adult was not angry or was not looking. These findings demonstrate that the infants interpreted the experiences of the first adult as relevant to themselves and applicable to their current situation. It also suggests that the 'Like Me' analogy does more than drive development through action imitation and revision – it also provides informational resources that can be applied to future situations.

Related Theoretical Work

In 1996, many of the principles of the 'Like Me' theory were applied and extended in a theoretical article authored by

Shaun Gallagher, a philosopher well known for his work on embodiment theory, and Andrew Meltzoff. This collaboration examined the human developmental emergence of *body schema* – the spatial representation of the body – and *body image* – the visual representation of the body. Movement and planned actions rely on body schema, which essentially informs one about where the body is extended in space and enables one to move accordingly. In contrast, body image is how one thinks the body looks while performing these actions (e.g., fat or thin, elegant or awkward).

Previous theorists proposed that body schema does not emerge until later in life by claiming that *aplasic phantom limbs* – the sensation that congenitally missing limbs are present – does not affect young children. Moreover, this schema is not completely tied to body image, since a visibly missing limb can be felt. Applying the 'Like Me' principles, Gallagher and Meltzoff (1996) determined that body schema is fundamental for understanding more complex phenomena, such as the self–other mapping. They hold that body schema provides an individual and extended point of reference for the actions of others to be mapped onto. In this respect, early development of body schema would allow children to map the actions of others cross-modally onto their own, whereas later development would theoretically preclude this ability. Thus, they argue that early emergence of imitation less than an hour after birth requires body schema as a prerequisite. This suggests that contrary to previous theories, body schema is innate. Body image is also necessary for imitation and therefore is likely also an innate ability. The neonate must be able to understand that when they see a researcher sticking out their tongue, this visual appearance (i.e., the body image) corresponds to the act of sticking out their own tongue (i.e., body schema). Although body image may not be completely tied to body schema, these frameworks are functionally intertwined during the act of imitation.

Applications and Implications

Mirror Neurons

Mirror neurons are proposed as one possible explanation for the 'Like Me' framework (Meltzoff, 2007a). *Mirror neurons* are cells in the frontoparietal circuits that specialize in sensorimotor integration. These cells become active when a person acts as well as when a person observes others acting. These neurons are hypothesized to provide a basis for empathy as well as for self–other mapping. By responding identically to actions performed by oneself and others, they are thought to establish a biological link between the behaviors of self and other. Although they have directly been observed in macaque monkeys, they have only been indirectly observed in humans and their function remains theoretical (Iacoboni and Dapretto, 2006).

Culture

Imitation appears to play a large role in sociocultural learning and has been implicated in the emergence in cross-cultural behavioral differences (Losin et al., 2009; Wörmann et al., 2012; Crafa and Nagel, in press). These differences emerge during early childhood, with culture-specific behaviors such as level of comfort around strangers and when to say 'thank you,' emerging during infancy (Keller and Otto, 2009; Wörmann et al., 2012). As the 'Like Me' theory explains, imitation drives child development and sociocultural learning. Children learn by observing, imitating, and improving upon behaviors they see their parents and other adults performing. Cross-cultural differences in the adult behaviors are also observed by children, and are therefore integrated into the child's framework (Crafa and Nagel, in press).

Cultural imitation may be partially influenced by shared cultures and appearance. Buttelmann et al. (2013) demonstrated that people were more likely to imitate others of the same cultural and racial background. Losin et al. (2012) also showed differential brain activity when imitating own race compared with other race people. This activity appeared to correspond with reported levels of familiarity with the other race, and these findings potentially suggest that familiarity is a key factor in cultural learning.

Disorders

Imitation and self–other mapping may also explain cross-cultural differences in the symptoms and behaviors corresponding with many psychiatric disorders. Crafa and Nagel (in press) propose that patients may exhibit different behaviors across cultures because (1) they are learning different cultural behaviors and (2) they may experiencing disruptions to functions underlying imitation or self–other mapping. According to this theory, actions and psychological states are not mapped exhaustively. Instead, only actions that are analogous ('Like Me') to a person are mapped. The underlying fodder for this 'Like Me' framework may be predetermined by biological predispositions and previous social experiences. Anomalies among these predispositions – such as atypical epigenetic or neural processes – may lead to differences in the fundamental self and therefore in the 'Like Me' framework that the other is mapped onto.

Autism

Autism spectrum disorder is hypothesized to emerge from a disruption to self–other mapping and the 'Like Me' framework. This idea was first proposed by Meltzoff (2007a) as one possible implication of the 'Like Me' theory. Lombardo et al. (2010) tested this proposal by examining neural processes associated with self–other mapping. They found that neurons in self-information processing areas of the brain behaved differently in people with autism diagnoses compared with people without autism. These disruptions potentially prevent or alter the mapping of representations of others onto the self in autism.

Counter Theories

In contrast with the proposal that self–other mapping acts as a foundation for interpreting others, other theorists suggest that interpretation of others' intentionality occurs prior to any cognitive representation. Tomasello et al. (2005) claim that

shared intentionality – the ability to share actions and goals with another person – gives rise to other cognitive representations, including the interpretation of another person as being 'Like Me.' According to this theory, many animals are able to understand the intentions of others, but humans uniquely can collaborate in the execution of these intentions. This ability to collaborate comes from two abilities that converge during early childhood: (1) the understanding that others are "animate, goal-directed, and intentional agents," and (2) the "motivation to share emotions, experience, and activities with other persons" (Tomasello et al., 2005: p. 675). Through a series of experiments, Tomasello et al. (2005) demonstrate that these two streams of abilities emerge during childhood at different rates. When they converge, around the age of 14 months, infants begin to display shared intentionality. Once developed, mental representations of others can then be constructed. This theory is fundamentally opposed to the 'Like Me' theory, by claiming that representations of others emerge later in infancy.

Research Prospects

With a few exceptions, research surrounding the 'Like Me' theory has focused on behavioral evidence during early childhood and a few neuroimaging studies in adults. Despite theorized relationships with mirror neurons and other neural events, the brain processes directly relating to the 'Like Me' phenomena have not been widely studied in infants or children. 'Like Me' behaviors have also not been studied in children diagnosed with autism, and such study could potentially benefit this research area as well.

Abstract

Born in Tunis in 1920, into a poor Jewish family, Memmi participated in the world of the colonizer and that of the colonized, a member of a subject minority within a colonized country. Memmi experienced a Nazi labor camp and worked for postwar Tunisian independence. His fiction and sociological essays extrapolate and theorize on the basis of his lived experience. Best known for *Pillar of Salt* (1953) and *The Colonizer and the Colonized* (1957), he has been a tireless advocate for the oppressed and analyst of personal and collective situations of dependency, domination, and racism.

Biographical Facts

Albert Memmi was born in 1920 in the city of Tunis, when Tunisia was a French Protectorate, into a Jewish family that was relatively poor, living (he implies) in a small alley off the slightly larger streets and alleys of the Jewish quarter of Tunis, *la Hara*, on the border of this neighborhood and those of other ethnic groups. Little remains of this quarter today as it was demolished under the guise of slum clearance in the 1950s. His father, who owned a small leather-working shop and with one assistant made harnesses and shoes, was from a family that might have had some Italian Jewish connections; and his mother came from a humble Jewish family that had always been in Tunisia. In other words, his father may have come from the *gorni* or Livornese, while his mother was from the *touansa* or indigenous Jews, two groups that hardly mixed until the twentieth century. The family spoke the Judeo-Arabic of Tunisia and Memmi's accounts of his childhood emphasize the relative deprivation he grew up in. For example (as recounted by Alexandre, the main character in his first novel), though he had to wear hand-me-down clothes, when he grew out of them they were passed on in turn – minus the buttons – to an even more deprived younger relative or neighbor. He recounts not having pocket money, not having enough lunch and snack money for school. Once he lent his two pennies for lunch to a rich boy who spent them on a chocolate bar that he then threw away, to Alexandre's (and obviously Albert Memmi's own) disgust and jealousy. Since the Muslim world was already in flux, the family also lived in fear of attacks on the *Hara* or Jewish quarter by neighboring Arabs. He attended the local Alliance Israélite Universelle school, where he picked up French and had the good fortune to win a scholarship to attend the prestigious Lycée Carnot high school of Tunis. There he had to confront profound cultural contradictions; for though inclined to study philosophy as one of its top students, as a sensitive teenager he was constantly wounded by the wealthy and non-Jewish students' lack of understanding of his position, poised uncomfortably between three civilizations: the North African/Middle Eastern, the Jewish, and the French.

Following the *lycée*, Memmi obtained an assistantship at the school in order to study philosophy in a correspondence course from the University of Algiers. During the war, under Nazi occupation between November 1942 and May 1943, like other male Tunisian Jews, he was rounded up and sent to a labor camp on the front where the Jews were forced to dig trenches against the Allied advance, under very dangerous circumstances. His novelized memoir, *La Statue de sel* (*The Pillar of Salt*), recounts a dramatic escape and trek to safety with a group of other prisoners and an attempt to join the Free French army. Though initially they did not want Jews, it seems that Memmi did eventually succeed in joining.

His later career is also rife with contradictions, which provide much material for the principled and reasoned stances he took in his writings and in his life. After leaving for Paris and the Sorbonne and graduating in philosophy in 1949, he returned to Tunis as an instructor at the technical college, together with his non-Jewish, French wife. His first novel, published in Paris in 1953, likewise caused a *succès de scandale* for its uncompromisingly realistic portrayal of Tunisian life. He also opened in Tunis an institute of psychology, whose patients must have provided him with much material for his subsequent novels and analytical works. Memmi actively supported Tunisian independence and was one of the founders of a weekly magazine, which was published "au service de la lutte nationale" ("in the service of the national struggle"), originally named *L'Action* (Action) and later *Jeune Afrique* (Young Africa).

After Tunisian independence, though, like many Jewish professionals, Memmi began to feel out of place in the new nation, which was attempting to define itself as a Muslim state; in 1956 at the age of about 36 (there has been some controversy as to exactly when he left, either in 1956 or 1957, but Memmi has informed me that he left in 1956. See my *Albert Memmi*, p. 42) saying that he felt his work in and for Tunisia was done, left again for Paris. A period of intense work began as he joined the Centre National de Recherches Scientifiques, and at the Ecole Pratique des Hautes Etudes headed a team of researchers. In 1970 he became a Professor of Sociology at the University of Nanterre; he has been associated with the Centre Universitaire d'Etudes Juives, was Vice-President of the Pen Club of France, and Director of the Centre de Recherches et d'Etudes sur la Dépendance. Thus, in combining philosophy, sociology, and psychology, as well as earning a reputation as a novelist, Memmi has always melded several disciplines in his search for truth. His commitment to Tunisia did not end with his second departure, and in 1984 he was awarded the highest honor of the Tunisian state, the Prix de Carthage, awarded personally by President Bourguiba himself. Memmi also supports idea that the Jewish people have a right

to self-determination (he describes himself as a "Zionist of the Left") and has visited Israel several times, a stance that probably has cost him some friends. In recent years he has traveled less, due to his late wife's illness, but in 2010 he visited Morocco to preside over a major conference on Jewish and Muslim interactions in the Maghreb, 'Migrations, identité et modernité au Maghreb.' Now in his nineties, despite recent bouts with illness and an accident, he continues to participate actively in the world of ideas. Memmi's experience has spanned the major traumas of twentieth century history (from anti-Semitism and the Holocaust to the struggle of a colonized nation for independence) leading him to diagnose the main sources of sociological and psychological distress and take courageous positions in favor of the oppressed, the colonized, the dominated, and those subject to racism.

Description of Major Works

Memmi's work naturally falls into two main groups, his fiction and poetry on one hand, and his sociological and philosophical writings, on the other. Despite the diversity of genres, his work as a whole has had a strong coherence over the years. It has reflected his opposition to the negative effects of colonialism, oppression, and racism and his support of attempts to achieve wholeness in the face of the fragmenting forces of cultural, political, and psychological schisms. He has been a builder of bridges, both within the individual, among individuals, and between individuals and social realities. He opened French minds to the idea that the French language could convey an entirely different mentality, world view, and aesthetic, those of the Maghreb. Always skeptical of received ideas and pieties, in later years through aphoristic writings, he advocated the view that personal happiness was nevertheless possible. These threads can be found running through the entire body of his fiction, poetry, and philosophical and sociological writing.

Since Memmi's first published book was a novel, we begin with his fiction. Writing *La Statue de sel* (*The Pillar of Salt*, 1953) was a psychological imperative for its author, who thought of it as a matter of survival. Writing was, for the young man who had just emerged from a forced labor camp and left for France, "a means of exorcism" (Yetiv, *L'Aliénation*: p. 160). Memmi believed that literature had a therapeutic function: by confessing, the writer frees himself from his obsessions. In Memmi's first novel, confession is as important as the aesthetic and the imaginary. However, as I have pointed out elsewhere, what appears to be autobiography in his novels sometimes has to be taken with a grain of salt, as the author deliberately does not tell us where biography ends and fiction begins. (See my 'Memmi's Introduction to History: *Le Désert* as Folktale, Chronicle and Biography,' *Philological Quarterly* 61:2 (Spring 1982), 193–207, esp. note 7, p. 205. Also Lia Nicole Brozgal, *Against Autobiography: Albert Memmi and the Production of Theory*, Univ. of Nebraska Press, Lincoln, 2013.) The success of Memmi's first novel was followed by a number of others, most of them also set in the Tunis of his young adulthood, such as *Agar* (Hagar, translated as *Strangers*, 1955); *Le Scorpion ou la Confession imaginaire* (*The Scorpion or the Imaginary Confession*, 1969); *Le Désert ou la Vie et les aventures de Jubaïr Ouali El-Mammi* (*The Desert or the Life and Adventures of Jubaïr Ouali El-Mammi*, 1977), set in medieval times, as the autobiography of an imaginary ancestor; *Le Pharaon* (*The Pharaoh*, 1988), set in postcolonial Tunis; and *Nomade immobile* (The Immobile Nomad, 2000). Memmi published one essay on literary theory, advocating different-colored typefaces for different voices within a novel: *L'Ecriture colorée, ou Je vous aime en rouge* (*Writing in Colors, or I Love you in Red*, 1986). His novels were never published in colored typefaces but he did achieve different typefaces for different voices or personae in *Le Scorpion* and *Le Désert*. He has also published short fiction, such as *Térésa et autres femmes* (2004) (Teresa and Other Women, 2006), and poems in various journals and one volume, *Le Mirliton du ciel* (*The Reed Pipe of the Sky*, 1985). These poems are very personal, with simple and homely language, relating on the one hand to relationships with old friends in Tunis and the traditional cycle of the Jewish year, and on the other hand including a number of love poems.

As he once admitted a little regretfully, he has been better known as an incisive essayist than as a belletrist. Memmi's early sociological writings brought him some notoriety in an age when the major colonial powers, particularly France, were still reluctant to set free their colonized subjects. His first nonfictional work, *Le Portrait du colonisé précédé du Portrait du colonisateur* (*Portrait of the Colonized Preceded by Portrait of the Colonizer*, 1957) became as well known as *La Statue de sel*. It was one of the first books to portray the psychological malaise of the colonized; over the years Memmi's name was linked with those of Octave Mannoni, Frantz Fanon, Aimé Césaire, and Jean-Paul Sartre, as one of the principal theorists of the colonial situation and as an advocate of decolonization. Memmi's theoretical writing in the field predated that of Fanon, since the latter's *Les Damnés de la terre* (*The Wretched of the Earth*) did not appear until 1961 (Fanon had previously published *Peaux noires, masques blancs* (Paris: Seuil, 1952). Memmi criticized Fanon's hypothesis of the *necessity* of violence as a purifying mechanism for new nations achieving independence. See '*La Vie impossible de Frantz Fanon*,' *Esprit* 9 (Sept. 1971, 248–273).

In his *Portrait du colonisé précédé du Portrait du colonisateur* (in the English edition, *The Colonizer and the Colonized*) Memmi described with great vividness the meaning of the negative image imposed on the colonized individual by the colonizer. Like the existentialists, he believed in the necessity of portraying concrete situations, and therefore concentrated on the experience of the individual. Lacking independent national institutions, the colonized man became simply the negative aspect of all the positive characteristics of the colonizer (himself deformed by the relationship) and the colonized man came to see himself in this same negative image. The colonized man ultimately attempts a 'recovery of self,' which is the refusal of the image imposed on him by the colonizer (p. 156) and eventually passionately rebels against the colonizer's culture. Such ideas, which were original and revolutionary in the 1950s, today have entered the general currency. Memmi followed this with several works in the vein of 'portraits,' giving us *Portrait d'un juif* (Portrait of a Jew, 1962) and his much later *Portrait du décolonisé arabo-musulman et de quelques autres* (Portrait of the Arab-Muslim Decolonized and of Several Others), titled in the English edition, *Decolonization and the Decolonized* (2004a). He described his method as a 'back-and-forth' between

a concrete situation that he knows intimately, where he is on sure ground having often lived it himself, and a generalizing hypothesis, a stylization that he constantly compares with the lived experience. Other writings, such as *L'Homme Dominé* (*Dominated Man*, 1968), describe the dominated and the dominators, in relations between masters and servants or men and women; and relations of dependency e.g., in *La Dépendance* (*Dependence*, 1979) either between two people who are dependent on each other (as in a marriage) or an individual's dependency on some perhaps unhealthy habit, such as drinking or smoking e.g., *Le Buveur et l'amoureux* (The Drinker and the Lover, 1998). In relations between Jews and Arabs, Memmi analyzed the psychologically unhealthy relationship of 'dhimmitude' (the subjection of a religious minority under Islam) and the need for Jews to have their own independent state in order to break this relationship, in *Juifs et arabes* (*Jews and Arabs*, 1974). Thus psychology and sociology have merged in his work. He has also analyzed racism and its manifestations, coining the term 'heterophobia' (hatred or fear of someone who is different). See *Le Racisme: Description, definition, traitement* (*Racism: Description, Definition, Treatment*, 1982). In later years, Memmi transitioned to a less critical stance, largely emphasizing the positive. He published three books on happiness, all in the 1990s; a *Dictionnaire critique à l'usage des incrédules* (*Critical Dictionary for the Use of Non-Believers*, 2000); his most recent book is his 'ethical will' *Testament insolent* (*Insolent Testament*, 2009).

Discussion of His Lasting Impact

Memmi's startlingly original ideas, emerging from painful personal experience and an uncompromising philosophical search for truth, have over the decades entered so fully into the mainstream of accepted thought in several fields that today they no longer strike us with their newness: it takes an effort to appreciate their originality. He was one of the first, together with Frantz Fanon, to diagnose the psychological malaise of the colonized as simultaneous with that of the colonizer (1957). In 1993, Edmond Jouve described the impact of Memmi's work when it appeared over 30 years before.: "Nous étions jeunes, et l'Algérie était en guerre. En vain, nous cherchions à comprendre. Et voice que … un nom s'inscrivit dans notre ciel: celui d'Albert Memmi. Et qu'un livre imposa à nous, qui nous délivra de nos peurs: *Portrait du colonisé*" ("We were young and Algeria was at war. We were trying in vain to understand. And then a name appeared: Albert Memmi, and a book came to us and delivered us of our fears: the *Portrait of the Colonized*.") (Jouve: p. 7). Memmi followed up his experience of anti-Semitism during the war years with one of his penetrating psychological portraits, the *Portrait d'un Juif* (*Portrait of a Jew*, 1962), which besides reflecting his lived experience is said to be influenced by Sartre's writing on anti-Semitism; this work was followed by the *Libération du juif* (*Liberation of the Jew*, 1966). In the field of Middle East studies or Maghrebian studies, the hypothesis of cultural fusion between Jews and Arabs originated with Memmi, as he described himself as an 'Arab-Jew' in *Juifs et arabes* (*Jews and Arabs*, 1974). He has been one of the few Jewish intellectuals who have been nevertheless welcome in some Maghrebian countries, such as Tunisia and Morocco; his earning the highest award of the Tunisian state in 1984 attests to a certain acceptance. Today, the widely used term 'Arab-Jew' is often applied to Jews who were obliged to leave Arab countries upon independence, but who still have some residual affinity or nostalgia for the culture of their countries of birth.

Recent approaches have valued Memmi's contributions as a theorist more than as a committed participant in sociological debates.

Memmi's contribution to the field of studies in racism is incontrovertible. Not long after arriving in Paris for the second time, he collaborated on a team effort, based on a questionnaire, and resulting in a book, *Les Français et le racisme* (*The French and Racism*, 1965). This book and a later one (*Le racisme*, 1982) also attempted a theory of racism which has informed similar studies to this day. Memmi was the originator of the term 'heterophobia' which covers racism and a broader range of the fear of those who are different from us in various ways. His *Dictionnaire critique* (Critical Dictionary, 2002) defines the term, the origins, and the psychology of racism. To note a difference is not a sign of racism, unless it is done in a negative way, he says. His brief definition is "racism is the general and definitive valorization of real or imaginary differences, to the advantage of the accuser and to the detriment of the victim, in order to legitimize aggression or privilege" (p. 285). Memmi sees the origin of racism in a fear of those who are different, causing preventive aggression. He also notes that racism and heterophobia are all the more tenacious because, as well as excluding the other, they also serve to reinforce our own membership in a particular group (p. 286). One can trace the influence of Memmi's thought (as well as of other thinkers, of course) in today's legal and institutional emphasis on the importance of encouraging tolerance of diversity in the workplace and on campus still sorely in short supply in both Western and non-Western countries.

The theory of dependency is also indebted to Memmi's thought. From *L'Homme dominé* (*Dominated Man*, 1973) through *La Dépendance* (*Dependence*, 1979) and to later works such as *Le Buveur et l'amoureux* (*The Drinker and the Lover*, 1998), Memmi elaborates on his definition of dependency as a constraining relationship (real or ideal) with another person, an object, a group or an institution, which the dependent individual more or less accepts, and which meets a need of the dependent person (my paraphrase from *La Dépendance* (Paris: Gallimard, 1979), p. 212). The concept of dependency as something undesirable has mellowed in his later writing where he discusses the need for mutual dependency within the couple. His later writings on happiness, often aphorisms, emphasize consideration and compromise toward those we love. Like many rational philosophers, Michel de Montaigne in particular, Memmi has tended, especially in his later works, to advocate the 'golden mean,' and moderation in all things, as a form of practical wisdom. Mutual dependency is thus linked to the idea of moderation.

Perhaps Memmi is still best known for his theory of colonialism – the toxic relationship which deforms both sides (the colonizer and the colonized, both those holding power and those who lack power) culturally, psychologically, and socially. The book had broad influence in the Third World, and even among 'dependent peoples' in Europe (Jouve: p. 9). Memmi extrapolated from his personal experience as a member of

a minority subjected by both the colonizers and the colonized in Tunisia, to a systematic analysis of the position of oppressed peoples in colonized countries – his book appeared at a time when many colonized peoples were achieving or struggling toward independence. He extended his well-known analysis of 1957 in a much later (2004) discussion of the 'decolonized,' depicting how the formerly colonized, even many years later, are still tainted by the original imbalanced and exploitative relationship. He described links within the new nations between poverty, corruption, and tyranny that may have offended some of his former allies. He also identified population shifts (migrations) and culture clashes between new and old nations, leading to a turn to political and religious myths, fundamentalism, and violence. As always, Memmi continued to advocate humanism and moderation in these struggles for identity. This work was received less enthusiastically than usual, due perhaps to readers' misapprehensions of what he was trying to say.

Memmi's thought has also had some influence in the area of language. From an earlier prediction of the death of the French language in new nations that France had formerly colonized, he came to recognize by the 1980s as a practical matter, the existence of the linguistic community of francophonie (Francophonia), which recognized that the French language no longer depended on the hegemony of France. His own work exemplifies this. Besides bringing a new reality to the literary consciousness of the metropolis from the 1950s onward through his fiction, he also edited a series of anthologies of francophone literature of the Maghreb. He has been recognized for this role with the Grand Prix de la Francophonie in 2004, awarded by the Académie Française for his work as a whole.

Memmi has also engaged in literary experiment in several of his novels. *Le Scorpion* has many layers and many voices, and Memmi's original plan, to differentiate between them by using different-colored printing, has been replaced by a series of different typefaces. However, he took up the subject again in a later volume entitled *L'écriture colorée*. This would seem to be an excellent idea for novels with multiple voices, such as *Le Scorpion* and *Le Désert*. He also favors frame stories, such as the discovery of manuscripts in the drawer belonging to the missing novelist, in *Le Scorpion*, or the aged prince telling his life story to Tamerlane in *Le Désert*: these devices constitute a modern version of the frame story of the *Thousand and One Nights*. The ambiguity between fictional narrator and the author's autobiography, which has often confused readers and critics of Memmi's fiction, also undermines the apparent verisimilitude of his novels and is decidedly disconcerting in a deliberately modern or postmodern way.

As a modern, engaged, taboo-breaking, secular writer, uncompromising in his willingness to discuss uncomfortable truths, Memmi could hardly be expected to be a supporter of tradition. Yet he has championed the traditional oral culture of the environment that he grew up in, the humorous tales of Djoha, tales of epic heroes, moral tales, folk wisdom, proverbs, a culture that was shared by the poorer Jews and Arabs in Tunisia. The multilayered novel *Le Scorpion* includes some references to Kabbalah. His novel *Le Désert*, set in medieval North Africa, the story of a deposed prince from a Jewish kingdom in southern Morocco, a fictional ancestor of the author, embodies many of these traditional elements and a kind of balanced and moderated wisdom that owes something to European philosophers and something to the age-old values of Tunisia that he grew up with. The structure of the novel resembles the frame story of Arabic literature. On his writing desk Memmi keeps several objects that remind him of traditional life in Tunisia: a piece of leather (recalling for him his artisan father's profession as a saddlemaker), scented amber, a Roman coin from Carthage. These he calls his *petite patrie portative* (little portable homeland), the objects that link him to his origins and inspire him to go forward to the ends of the world.

Memory Binding

Richard J Allen, University of Leeds, Leeds, UK

© 2015 Elsevier Ltd. All rights reserved.

Abstract

How are the constituent features of elements within the environment bound together in memory to form integrated or associated representations? A body of research has started to emerge examining this broad question, with important implications for how we experience the world around us. The present article explores binding and relational processing across a range of contexts, taking a cognitive perspective in focusing on different forms of binding within working memory and relating this to long-term association formation, before considering how the brain might achieve memory binding.

The objects of memorial processing – visual and auditory stimuli in the environment, for example – typically consist not of meaningless and unidimensional features, but of multiple, often disparate elements, associated with context and current task goals. In the visual domain, for example, objects are made up of multiple configurations of shape, color, and size (e.g., fruit and vegetable selections in a supermarket). Similarly, when processing linguistic information, elements are normally embedded within the context of a meaningful flow of information, rather than as isolated fragments. In each case, elements of the experience must be bound together to form coherent representations in memory, in order to be understood and to potentially influence further action. More broadly, episodes in our lives are typically experienced as integrated occurrences in which information from across modalities and feature dimensions are brought together to form stable and meaningful experiences, rather than random and chaotic sensory noise. Each of these involves processes of *binding* in memory, that is, drawing together and integrating information from different environmental sources and the neural areas responsible for initially processing them.

For the purposes of the present work, binding is used as an overarching term to denote situations in which different forms of information are integrated together in memory. It is assumed that within this, multiple and separable forms of binding can be distinguished, each serving different contexts and types of element. As will be discussed, these are likely to involve differing cognitive processes and draw on distinct neural areas. Binding links to, and is sometimes used interchangeably with, terms such as chunking, grouping, association formation, and relational and conjunctive processing. For example, chunking can refer to an active, strategic method of linking elements together on the basis of prior semantic relatedness, summed meaning, or perceptual features (Miller, 1956). While all these terms refer to the identification or creation of connections between elements (with resulting gains to memory from information compression), it is probably not appropriate to collapse the meanings of these terms together or equate them simply with memory binding. However, such concepts are often relevant when discussing how binding might operate and help in placing such processes in the context of wider cognitive functions. Indeed, they may in some cases reflect fruitful ways of differentiating between subcategories of binding process. Therefore, in some cases they are assumed to reflect forms of binding (e.g., relational and conjunctive processing), while in others they bear relation to binding but are not functionally equivalent.

The question of how information binding is achieved has often been termed the 'binding problem,' primarily in the perception literature (Treisman and Gelade, 1980) but more recently in the context of working memory (WM) and long-term memory (LTM). It is often characterized as being problematic due to the different brain areas and parallel functions thought to be involved in initial processing of sensory information (e.g., form, location, audition, etc.). Solving this problem or, more likely, collection of problems involves adopting perspectives from across cognition psychology and neuroscience (among others) in exploring how these forms of information are processed and integrated, from low-level perceptual integration, through more active and effortful processing and manipulation in WM, up to the integration of rich tapestries of information to be held in LTM, as well as identifying ways in which these levels tie together. It is clearly highly informative to explore how information binding is achieved, as this provides insights into key issues such as the nature of representations in memory, processes of encoding, maintenance, and retrieval, the role of attention, the structure and function of memory, and also helps characterize how memory changes across the lifespan and the nature of deficits that exist in patients with different forms of brain injury or disease. Each of these issues will be briefly covered, in the context of information binding.

Binding in Working Memory

A major focus of recent research has explored how binding processes might operate within WM, that is, the system responsible for temporarily maintaining, processing, and manipulating information from the environment and relating it to prior knowledge. A number of WM models have been proposed and subsequently developed in the literature which, while differing in important ways (e.g., on existence of fractionable, domain-specific subsystems, and how WM and LTM may be related), each emphasize the limited capacity of WM, it's close links with perception, attention and LTM, and the central role of WM in wider cognitive function. Until recently, however, these models did not attempt to explicitly capture information binding. Newly emerging work indicates this may

be a crucial factor in determining limits to WM capacity, the nature of representational storage, and the success with which these representations are created and subsequently retained or lost over time.

Visuospatial Binding

As stated above, the issue of binding has been highlighted for some time in the area of visual perception, concerning how distributed neural codes representing elements within a visual scene are combined to support accurate perception of objects such as a red apple next to a green leaf, rather than a red leaf and a green apple (Treisman and Gelade, 1980). How then might the binding of visual and spatial features such as shape, color, orientation, and location be achieved in WM? This question is often assessed in controlled experiments by presenting participants with arrays of stimuli (often simple objects, to minimize impact of preexisting associative knowledge) and requiring various forms of recognition or recall response (see Figure 1).

One possibility is that, as in perceptual tasks, focused attention is required for features to be successfully and accurately bound together. It is indeed likely that one sense of focused attention, that is, spatial attention, is critical for binding in visual WM. This can be distinguished however from a more domain-general set of attentional resources involved in active, strategic processing, tied to the concept of a central executive. In a revision of the multicomponent model of WM, Baddeley (2000) suggested that active and attention-demanding binding was a key role played by the episodic buffer, a storage component claimed to be involved in binding information from different sources (e.g., separate phonological and visuospatial subsystems) and linking with LTM. However, while the episodic buffer (or an analogous component) may play a role as a passive recipient of prebound representations, research to date has failed to consistently support the notion of an attention-dependent binding process in visual WM. For example, Allen et al. (2006) examined memory for shapes, colors, and shape–color conjunctions while performing simple or more demanding (e.g., backward counting) verbal tasks (intended to disrupt availability of attentional resources) concurrently during presentation and a short retention interval. It was found that the conjunction conditions (measuring binding), in which participants were required to decide whether a color–shape combination had been present in a previously presented display (see Figure 1), were no more affected by this attentional manipulation than single feature memory (in which participants simply decided whether a test shape or color had been encountered). It appears then that, at least for simple unitized objects that are briefly encountered, binding may be achieved relatively automatically, with attention only important for processing constituent features (Baddeley et al., 2011). However, the constraints that apply to this automaticity are yet to be fully mapped out.

Figure 1 Illustration of typical presentation and test methods used to assess binding of color and shape in visual working memory. To-be-remembered array (a) is briefly presented, followed after a short delay by the test phase. Across different studies, this might involve (b) whole-display change detection recognition, requiring detection of any change in feature conjunctions (normally via key press or button box), (c) single probe recognition, requiring a decision on whether this combination had been present in the display, or (d), cued recall, requiring verbal recall of, for example, which color was presented with the test shape. Similar methods can be implemented to assess other forms of binding, for example, between feature and location. Note that other methods of presentation and assessment have also been utilized, and comparison with memory for constituent features must always be considered.

When unitized objects such as colored shapes are encountered, what is the nature of their representative format? In their seminal work, Luck and Vogel (1997) observed that change detection judgments for features within briefly presented visual arrays were as accurate when objects varied along four different feature dimensions (e.g., color, orientation, size, and presence of a gap), compared to a single dimension, with performance declining as number of distinct items increased. Based on this, Vogel et al. (2001) argued that visual WM representations are object based, with capacity limited (at around three bound objects; Cowan et al., 2012) by number of objects rather than number of features. In contrast, Wheeler and Treisman (2002) suggested that visual WM instead consists of separate feature stores, with the bindings between them being particularly vulnerable to loss caused by attentional withdrawal; thus, attention is important for maintenance of conjunctions between constituent parts. In line with this, Allen et al. (2006) found that bindings are fragile and liable to interference from subsequently encountered stimuli; memory for conjunctions was disproportionately worse when stimuli were presented sequentially, as opposed to simultaneously. However, a range of research has suggested this fragility to be independent of available attentional resources; adding a concurrent load or directing attention elsewhere in the visual scene in the retention delay between presentation and test disrupts performance, but generally not for binding any more than individual features (Morey and Bieler, 2012). Furthermore, Ueno et al. (2011) have demonstrated that binding is fragile even when subsequently encountered interfering stimuli are

to be ignored, indicating that it is not the active encoding of these stimuli into WM that causes loss of bound representations, but their basic presence in the environment and resulting perception.

Cowan et al. (2012) have recently suggested that bindings in memory can break down and lose features independently of each other, leaving partial representations that lack some of their original elements (e.g., we may remember that a *red* object was present, but not that it was a *triangle*). They examined memory for features and their bindings across a range of encoding and retrieval conditions, and found evidence of a fixed object limit (of around three items), but incomplete retention of attributes from these objects. Other studies (Bays et al., 2011) have also observed partial loss of an object's features from memory, and interpreted this instead as evidence for precision based as opposed to object-based constraints on WM, though this issue is somewhat outside the scope of the present review. Nevertheless, it is emerging that objects are not always retained in an all-or-none way, and partial feature loss can occur.

So far, discussion has focused on processing of visual items that are 'unitized,' that is, encountered as single unitary objects in the environment (as in **Figure 1**). It is informative to examine how attributes are bound in memory when they are not clearly part of the same object. The question of what constitutes an object is too broad for the current review, though it is worth noting that studies have highlighted principles such as boundedness, connectedness, temporal contiguity, and shared spatial location (Kahneman et al., 1992). In line with this, it is likely that the processes involved in binding vary depending on whether features are 'unitized' in the environment. For example, a number of studies have demonstrated that visual features are better remembered when presented within the same object and spatial location, as opposed to when they are spatially distinct. Similarly, binding between surface features such as color and their spatial locations, and binding within feature dimensions (e.g., between adjacent colors) may behave differently to unitized shape–color binding, for example, in terms of relative accuracy levels in recognition tasks and whether they show consistent decrements with healthy aging (see Section Neural Basis of Binding).

Related to this, a distinction has recently been drawn between *intrinsic* and *extrinsic* binding (Ecker et al., 2012). The former is equivalent to unitized binding, concerning information, that is, intrinsic to a perceptual unit (e.g., an object's color), while the latter relates to binding of contextual information that is part of the overall event (e.g., the color of another object present alongside the target). Ecker et al. observed that memory for shapes was only disrupted when task-irrelevant changes in color were intrinsic to the target (i.e., part of the same object), and not extrinsic (i.e., part of the scene background). In line with previous work (Baddeley et al., 2011), Ecker et al. (2012) argue that intrinsic binding occurs in an obligatory and automatic fashion, while binding of extrinsically related features does not and may instead require active and strategic encoding. This distinction may mirror those operating during perception and in long-term episodic memory, with binding of extrinsic and contextual details possibly representing a major constraint on WM capacity. Connected to this, work by Oberauer and colleagues (Oberauer et al., 2008) has suggested that such forms of binding and relational processing may be closely linked to individual differences in WM capacity, reasoning, and fluid intelligence. They argue that WM is itself a system primarily for constructing relational information in the form of temporary bindings between separate components of a scene or episode.

Cross-Domain and Cross-Modal Binding

Unitized binding appears to be relatively automatic (though fragile), while some other forms of visual binding, particularly those potentially characterized as extrinsic or relational in nature, may require additional processes and potentially distinct types of binding for features to be connected in memory. In addition, it is possible for information from different domains (e.g., verbal and spatial) and modalities (visual and auditory) to be bound in memory (e.g., remembering the location of captions placed on an image, or a group of people's names). These forms of binding represent a particularly strong test of the episodic buffer concept (Baddeley, 2000), in linking together separate information streams in WM. Other theoretical approaches to WM that do not emphasize independent subsystems do not require such a concept, though they still require further development in order to effectively capture these abilities.

There is somewhat less work on such forms of binding at present. Elsley and Parmentier (2009) examined the role of attentional control in letter–location binding in WM, and found that memory judgments concerning letters and locations were faster and more accurate when initially presented in conjunction (as opposed to being part of separate 'objects'), but this binding effect was considerably reduced when a demanding tone-judgment task was concurrently performed. On this basis, Elsley and Parmentier argued for an attention-demanding cross-domain binding process, in line with Prabhakaran et al.'s (2000) observation of greater prefrontal activation in trials involving integration of letter and location. This might suggest that binding across domains is more akin to extrinsic than intrinsic binding in terms of attentional demands, although more work is required to explore the constraints on automaticity in this regard. Nevertheless, these findings indicate that binding letters to spatial locations in memory can benefit memory for the constituent elements, perhaps through reducing memory load or enhancing access at retrieval. A similar finding has been demonstrated using verbal recall; Darling et al. (2012) demonstrated that verbal digit recall is improved when digits are presented within certain spatial configurations, as opposed to single locations. Importantly, this verbal–spatial binding was shown to be crucially dependent on whether these associations were already present in LTM, as the effect only emerged for digits presented in typical numerical keypad displays (as found on keyboards and telephone interfaces), and not when the digits were randomly reorganized within the same overall configuration. Thus, implicit verbal–spatial binding appears to support recall of verbal information only when the participant has preexisting knowledge of such associations.

While examining binding across domains, these studies still involve integration of information presented within the same modality (i.e., visual). What about binding of information across modalities (e.g., between vision and audition)? Participants do seem to be able to make recognition judgments concerning associations between sequentially presented visual stimuli (e.g., shapes) and aurally presented verbal labels (color names), as accurately as to unitized colored shapes (see Baddeley et al., 2011). Binding between audition and spatial location is also possible; we are able to localize sounds such as speech both in perception and memory. Maybery et al. (2009) observed consistent evidence for memory of the binding between aurally presented letters or nonverbal sounds and which of the locations they were presented from, noting greater persistence for such conjunctions than in visual feature binding (Allen et al., 2006). Further work is required to establish how such integration takes place, and whether additional processes are required above and beyond simple feature binding within modalities.

Verbal Binding

Although involving different representational forms and types of processing to those outlined so far, it is also possible to identify binding during purely verbal tasks. This may operate in a hierarchical fashion, with binding between components such as syllables and phonemes, between elements and their position in a sequence (potentially via temporal or ordinal context signals), between words in the formation of meaningful phrases and sentences, and between concepts in order to form mental models and representations of complex episodes.

The established observation that memory for meaningful sequences such as sentences is more accurate than for random lists of words may reflect a further form of information binding (though interchangeable use of the terms binding and chunking is more prevalent in this area). Baddeley et al. (2009) examined the contribution of attentional resources to sentence and word list processing using concurrent verbal and visuospatial tasks of varying levels of difficulty. It was concluded that use of linguistic structure and redundancy in the binding between elements of a sentence in order to form larger cohesive segments appears to develop relatively automatically; while demanding concurrent tasks had large effects on performance, they did not reduce the recall advantage for sentences over lists. This advantage necessarily involves access to linguistic knowledge concerning meaning and grammatical structure in LTM, with subsequent storage of bound segments or chunks potentially held in WM within a component such as the episodic buffer.

While Baddeley et al. (2009) examined within-sentence binding, Jefferies et al. (2004) explored binding across sentence boundaries, comparing memory for short sets of sentences that were either presented within the context of a meaningful narrative, or in a random, meaningless order. In relation to the impact on memory for random word lists, a concurrent visuospatial task (intended to load on attention) did have a significantly larger disruptive effect on unrelated sentence memory. However, this was not the case for related sentence sets presented in the context of a narrative. Thus, binding or chunking together meaningful concepts across sentence boundaries does seem to require additional attentional resources, but only when the connections between these segments need to be newly constructed and do not fit into a schematic narrative.

Binding and Association Formation in LTM

Discussion has focused primarily on binding over the short term, within working memory. As it is plausible to regard WM and LTM as separate constructs (Baddeley, 2000), how then might more robust, long-lasting representations be created, and how does this relate to the studies outlined above? In terms of verbal conjunctions, temporary bindings in WM may be translated into LTM-based associations, perhaps through a gradual process of Hebbian learning (Baddeley et al., 2009). A similar process was described for the binding of shape and color in visual memory by Logie et al. (2009), with repeatedly presented bindings gradually leading to longer-term residual traces of object representations, although this learning process was very fragile and liable to disruption from new presentations on later trials. Thus, while functionally independent, it is likely that binding processes and representations in WM and LTM are mutually supportive and to some extent share representational formats.

Hommel and Colzato (2009) distinguished between the formation of new, arbitrary binding in WM (e.g., *red-circle*) and familiar conjunctions in LTM (e.g., *red strawberry*). They do note, however, that in each case binding is automatic. Indeed, development of long-term associative memory representations can, in some cases, operate without specifically relying on attention. Naveh-Benjamin and colleagues (Naveh-Benjamin et al., 2003) have shown that associative memory for unrelated word pairs, nonword pairs, or word and presentation context pairings is not particularly affected by divided attention during encoding. This fits with certain forms of automatized binding and chunking in WM (Baddeley et al., 2011), though it may be that temporary chunking of previously unrelated verbal pairs in WM does still draw on attentional resources. Again, it is likely that key processes vary with the particular nature of the task and the form of binding being examined.

One consistent parallel emerging between binding in WM and LTM relates to the intrinsic–extrinsic distinction discussed by Ecker et al. (2012). Zimmer and Ecker (2010) have outlined a model of LTM that distinguishes between object tokens (containing intrinsic detail only) and episodic tokens (involving both intrinsic and contextual extrinsic information). Such a distinction has many similarities with that often drawn between conjunctive and relational integration (Moses and Ryan, 2006). Ecker et al. suggest that this may be fundamental across tasks ostensibly measuring perception, WM, and LTM. Indeed, unitization effects (i.e., superior memory for conjunctions of color and shape when part of the same object) have been observed in long-term recognition tasks that may be analogous to those reported in WM. Therefore, as in the case of WM, it may be that only LTM tasks requiring memory for extrinsic binding information (including context) are affected by divided attention

manipulations. How this explanation maps onto the forms of binding previously described remains to be explored.

Neural Basis of Binding

It is important, of course, to map out the neural as well as the cognitive underpinnings of memory binding. Discussion of how the brain achieves memorial binding has focused on two different questions: how and where. In terms of the former, Hommel and Colzato (2009) identify convergence and synchronization as two principles that have been particularly influential in describing how conjunctions are represented at the neural level. Convergence describes a hierarchical system in which lower level neurons code for simple features (e.g., shape or color) that project onto higher level neurons that code for conjunctions, which in turn may feed to higher levels for objects. As often noted, however, a system purely based on this principle would suffer from the problem of combinatorial explosion (i.e., there are too many possible feature combinations for each to be represented individually). Synchronization, in contrast, is the suggestion that neurons representing individual features achieve binding by firing in temporal synchrony (Vogel et al., 2001). Hommel and Colzato (2009) have suggested these principles may operate together, with convergence more likely to support memory for familiar feature conjunctions (e.g., yellow banana, red strawberry) while synchronization is more important for arbitrary conjunctions (e.g., yellow circle, red square).

Irrespective of function at the neural level, where in the brain might different forms of binding be based? It is established that many forms of relational or conjunctive processing rely on the hippocampus within the medial temporal lobes (Moses and Ryan, 2006; O'Reilly and Rudy, 2001). This certainly seems to be the case for LTM, with binding or associative memory between constituent elements of an episode being impaired in patients with hippocampal lesions and showing increased activation in studies using PET and fMRI, relative to single elements (Cohen et al., 1999). Thus, in line with the critical role it is thought to play in supporting episodic memory and recollective experience (including memory for contextual detail), the hippocampus is central for LTM binding. As hippocampal function is known to deteriorate with healthy aging, this may explain why older adults show an associative memory deficit in LTM (Naveh-Benjamin et al., 2003), displaying particular problems acquiring new associations between paired stimuli of different types (e.g., words, pictures, and faces). Similarly, Alzheimer's disease is associated with hippocampal degradation, and tasks measuring learning of new associates in LTM (such as the paired associates subtask of the CANTAB (Cambridge Neuropsychological Test Automated Battery), in which participants are required to learn sequences of shape–location pairs) appear to be a particularly sensitive method of identifying individuals with dementia.

The role of the hippocampus appears to be more compelling for extrinsic or relational binding, as opposed to intrinsic/conjunctive binding (Ecker et al., 2012; Moses and Ryan, 2006). Indeed, Ecker et al. argue that anterograde amnesia, typically associated with hippocampal damage, may not be an LTM impairment, but instead reflects a deficit in extrinsic binding. If this is the case, the hippocampus should also be crucial to certain forms of temporary binding in WM tasks (e.g., those requiring binding between objects, or to location), and this is indeed what has been reported across several studies using fMRI or examining patients with medial temporal lobe damage (Olson et al., 2006; Mitchell et al., 2000; though see Ryan and Cohen, 2004). Similarly, certain age-related deficits in binding between items and their spatial locations in WM tasks have also been observed (Mitchell et al., 2000), which may also at least partly reflect medial temporal lobe decline.

In contrast, other forms of binding in WM, for example, between shape and color, appears to be intact in individuals with selective hippocampal damage. One such patient, Jon, was shown to perform extremely well on a battery of tasks assessing WM for sequentially presented color–shape conjunctions of various forms (Baddeley et al., 2010). Evidence regarding older adults' performance on such tasks is mixed to date (Brown and Brockmole, 2010), though on balance also indicates that healthy aging is not consistently and robustly associated with particular problems in shape–color binding in the same way that long-term relational binding appears to be, and thus may operate independently of age-related hippocampal decline. Recent research is also emerging to indicate that measures of binding (e.g., between shape and color) within WM may also serve as particularly useful preclinical markers in detecting the onset of Alzheimer's disease (Parra et al., 2010) They examined a group of related individuals with a gene mutation (E280A in *presenilin-1*) that always leads to this disease, and observed deficits in a task requiring WM for shape–color binding in carriers of the mutation who were either diagnosed with Alzheimer's disease, or were asymptomatic. Healthy relatives without the gene mutation did not show this binding deficit. As already stressed, this impairment is likely separable from more established hippocampal-based LTM deficits, and may instead be attributable to a wider loss of brain connectivity in Alzheimer's disease that may be important in this task. Nevertheless, the emerging use of such tasks in the early detection of individuals with potential cognitive impairment is an example of how developments in methodology and theory can feed into beneficial impacts on society.

It is clear that areas of the prefrontal cortex are important across the majority of memory tasks, given this area's potentially diverse and critical roles in executive function and attentional control. What is less clear, however, is whether the prefrontal cortex might specifically have a function in information binding. As noted earlier, Prabhakaran et al. (2000) used fMRI during a task aimed at measuring letter and location memory and found evidence to suggest that the prefrontal cortex, specifically right BA 10, may be highly activated when letter–location conjunctions are processed. Similarly, in their study of young and older adults, Mitchell et al. (2000) observed increased activation in the same area of the prefrontal cortex (as well as hippocampal activity) in a task measuring shape–location binding in WM. On this basis, Mitchell et al. argued for a frontal-hippocampal binding circuit, though noted that the precise contribution of right BA 10 to binding remains unclear (as this area is different from

those typically identified as being involved in maintenance, manipulation, or sustained attention). In each of these cases, however, further research is required to corroborate and more closely specify the precise areas that may be involved.

A further area that may have a potentially important role in information binding is the parietal cortex. Shafritz et al. (2002) used fMRI to demonstrate increased activation in parietal areas normally involved in spatial attention (right superior parietal and anterior intraparietal), when binding conjunctions of shape and color, though only when location was available as a cue, thus supporting Treisman and Gelade's (1980) claims of a central role for location in visual binding. As WM may be closely tied to the products of perception, links can be drawn with observations of shape–color binding problems in perceptual tasks reported by patients with bilateral parietal lesions (Friedman-Hill et al., 1995). Indeed, areas of the parietal cortex including the intraparietal sulcus have been identified as being crucial for working memory storage more generally, possibly reflecting integration of information from within and across modalities as part of a frontoparietal network.

Overall, it is likely that different networks of brain areas are critically involved in memory binding, but as with patterns of findings from empirical research, this likely varies with features of the memory task, depending on stimuli, type of binding required, and relative loads on temporary storage and LTM, amongst other factors. As well as frontal-based control, the available evidence strongly suggests a crucial hippocampal involvement for LTM, though this is less clear for WM tasks, which may also (or alternatively) draw on parietal contributions for storage.

Summary

Binding, while used here as a single overarching concept, relates to disparate sets of processes within and across domains. Recent work has started to specify its nature and function in each case, and in doing so has provided important new insights and constraints for theories of memory. In addition, studies have started to explore ways in which memory binding varies with healthy cognitive aging, disease, and brain damage. In this way, developing a full picture of how information binding operates is potentially very useful not only for informing theory, but also for identifying, understanding, and potentially remediating cognitive impairment.

Abstract

Our autobiography is composed of memories from our past and plans for our future. Most adults' earliest autobiographical memories date from between 3 and 4 years of age and the absence of memories from before this age is referred to as infantile or childhood amnesia. This article traces memory development from the emergence of memory during infancy to the emergence of autobiographical memory in early childhood.

> This is the use of memory:
> For liberation – not less of love but expanding
> Of love beyond desire, and so liberation
> From the future as well as the past.
> T. S. Eliot (1943)

As T.S. Eliot (1943) notes, memory liberates us from being bound solely to the past, present, or future; it allows us to travel between these epochs in time and, in doing so, allows us to construct our autobiography. An autobiography is composed of not only memories from the past but also thoughts of the present and plans for the future. To adults, these aspects of memory are second nature but, when thinking about our personal past, just how far back can we go? And, if we can only go so far back, does that mean that at some point in our lives we did not have *memory*? The answer to the first question is clear; most adults' earliest autobiographical memories date from between 3 and 4 years of age (e.g., Davis et al., 2008; Jack and Hayne, 2007, 2010; Jack et al., 2012; Sheingold and Tenney, 1982). The almost universal absence of autobiographical memories from before this age is referred to as infantile or childhood amnesia (Freud, 1963). With respect to the second question, the answer is also clear. Although our early past cannot be recalled as adults, even very young infants are able to encode, store, and retrieve memories after significant delays (e.g., Barr et al., 1996; Hartshorn et al., 1998; Hayne et al., 2000, 1986). Having no *autobiographical memories* from a time when we once had *memory* may seem somewhat paradoxical; it simply reflects the complex nature of memory development. This article traces memory development from the emergence of explicit memory during infancy to the emergence of autobiographical memory in childhood.

What Is Memory?

There is general consensus that there is more than one type of memory (cf Roediger, 1984; Snodgrass, 1989). Typically, a distinction is made between explicit and implicit memory (Graf and Schacter, 1985), also referred to as declarative and nondeclarative memory (Squire, 1992). Essentially, theorists draw a distinction between memories that people are consciously aware of (i.e., declarative or explicit) and those that they are not (i.e., nondeclarative or implicit) (Hereafter we will use the terms implicit and explicit, as these are the terms most commonly used in the developmental literature (Hayne, 2004; Rovee-Collier et al., 2000).) This distinction was largely born out of experiments with people who became amnesic as a result of the removal of, or damage to, the medial temporal lobe (Scoville and Milner, 1957). These patients displayed profound amnesia for recent events and, highlighting the pivotal role of the hippocampus in memory, the degree of impairment was positively related to "… the extent of destruction to the hippocampal complex" (Scoville and Milner, 1957: p. 20). Critically, follow-up experiments with one patient established that he still displayed memory for simple perceptual and motor tasks (Corkin, 1968, 1984, 2002; Milner et al., 1968). The patient learned these tasks over several laboratory visits, suggesting that the learning from one visit carried over to the next, despite the fact that he could not recall his previous visit to the laboratory or the task that he performed. This clear memory dissociation was explained by appealing to a dual memory system, with the medial temporal lobe being critical for explicit memory, such as memory for daily life events, while implicit memory is supported by brain regions outside the medial temporal lobe (Cohen and Squire, 1980; Tulving and Schacter, 1990).

Schacter and Moscovitch (1984) were the first to apply this dual memory view to memory development, arguing that the implicit memory system is functional at birth and that the explicit memory system becomes functional between 8 and 10 months of age. Some authors have supported this view (Carver and Bauer, 2001; Richmond and Nelson, 2007), whereas others have argued that the implicit and explicit memory systems develop simultaneously rather than sequentially (Rovee-Collier et al., 2000), that the explicit memory system is preceded by a preexplicit system (Nelson, 1995), or that a dual memory system is not needed at all

to explain infant memory development (Rovee-Collier and Cuevas, 2009). While these authors disagree on exactly when during development the explicit memory system is functional, there is clear agreement that it is functional by 12 months of age.

Assessing Explicit Memory across Development

One obvious question is how can explicit memory be tracked across development? Young children's limited language skills mean that one cannot simply ask them to tell what they remember. Over the past several decades, developmental psychologists have come up with some ingenious tasks that allow young children to nonverbally convey their explicit memory skill. These tasks include both deferred (Meltzoff, 1995) and elicited (Bauer and Mandler, 1989) imitation paradigms, and conditioning tasks, such as the mobile conjugate (Rovee and Rovee, 1969) and train (Hartshorn and Rovee-Collier, 1997) reinforcement paradigms. While each of these paradigms has made a significant contribution to the study of memory development (see Hayne, 2004; Rovee-Collier, 1997; for reviews), they do require procedural changes when assessing memory in participants of different ages. For example, the complexity and number of actions in imitation tasks must be altered to equate for task difficulty across ages. Similarly, while the mobile conjugate paradigm is appropriate for use with infants up to 7 months of age, it must be substituted with the train paradigm to assess memory in older infants and young children.

Among developmental memory paradigms, the visual paired comparison (VPC, Berlyne, 1958; Fantz, 1956) paradigm is unique in that the exact same stimuli and procedure can be used with infants, children, and adults. In the VPC paradigm, participants are familiarized with a visual stimulus, and after a delay, they are presented with a pair of visual stimuli – the stimulus they viewed during familiarization and a novel stimulus (**Figure 1**). Memory is inferred if participants spend a greater proportion of time looking at the novel, relative to the familiar, stimulus. This preference for the novel stimulus is thought to be the result of participants recognizing the familiar stimulus and, consequently, directing more attention to processing the novel one. This interpretation is based on Sokolov's (1963) comparator model, which holds that participants attempt to match each stimulus they encounter to a stored representation. If a match is found, attention to that stimulus is inhibited, whereas if no match or a partial match is found, then attention is maintained. Despite the relative simplicity of the task, there is a growing body of neurophysiological and developmental work supporting the view that the VPC paradigm provides a measure of explicit memory. For example, patients with damage to the hippocampus show substantial deficits on the VPC paradigm when tested after a delay (McKee and Squire, 1993; Munoz et al., 2011; Pascalis et al., 2004). Furthermore, using Tulving's (1983) principle of experimental dissociation, researches have shown that the same variables that influence adults' performance on a wide range of explicit memory tasks also influence infants' performance on the VPC paradigm.

Explicit Memory Development

Although the VPC paradigm has historically been used with very young infants (Fantz, 1956), the authors have recently used it to trace the development of explicit memory during infancy and early childhood. All their work with the VPC paradigm was carried out using an apparatus that consists of a three-sided enclosure, covered in black felt, with two 21-inch monitors mounted to the back panel of the enclosure. The monitors are positioned 46 cm apart and a low-light video camera, also mounted to the back panel of the enclosure, is positioned between them to allow for off-line coding of infants' looking. In all the studies described here, specially designed stimuli, consisting of computer-generated three-dimensional cartoon faces – a blue mail-box shaped face, a yellow circular face, and a red square – were used (see **Figure 1**). During presentation, the faces either blinked their eyes or moved their mouth. Although some researchers have argued that the VPC paradigm may not be suitable for young children (Atkinson, 2000), the authors' use of animated stimuli has all but eliminated participant attrition due to a lack of interest. Over the past few years, this task has been used to study age-related changes in encoding, retention, and retrieval.

Encoding

Prior research has shown that the speed with which infants encode information increases considerably over the first 6 months of life (Davis and Rovee-Collier, 1983; Greco et al., 1986; Hill et al., 1988). Using the VPC paradigm, Morgan and Hayne (2006b) traced age-related changes in encoding time from infancy through early childhood. In their study, separate groups of 1- to 4-year-old children received either a 5- or 10-s familiarized period and were then tested either immediately or after a 24-h or 1-week delay. Note that the immediate test provides a pure measure of encoding. When the familiarization period was just 5 s, 1-year-old children did not display a novelty preference even when they were tested immediately after familiarization. This finding suggests that, for 1-year-olds, the 5-s familiarization was simply not sufficient for them to encode the stimulus. The 4-year-old children, on the other hand, exhibited a novelty preference when tested immediately and after the 24-h delay. When the familiarization period was 10 s, both the 1- and 4-year-old children exhibited retention when tested immediately, but only the 4-year-old children exhibited retention after the 24-h and 1-week delays.

The fact that the 1-year-old children displayed a significant novelty preference only when the familiarization period was 10 s, and that the novelty preference was only observed when they were tested immediately, suggests that 10 s may be the minimum amount of time 1-year-old children require to encode a stimulus on the VPC paradigm. By 4 years of age, however, a 5-s familiarization period is sufficient for encoding. The additional finding that 4-year-old children's retention increased when the familiarization time was increased from 5 to 10 s suggests that encoding is not an all-or-none phenomenon, a point that is touched on when discussing long-term retention.

Figure 1 An example of an experimental trial. Top panel: familiarization phase in which identical stimuli are displayed on both screens. Middle panel: Trial 1 of the test phase, with a novel stimulus presented on one screen and the familiar stimulus presented on the other screen. Bottom panel: trial 2 of the test phase in which the right and left positions of the test stimuli are switched. The animated stimuli are provided in the multimedia annexes.

Long-Term Retention

The duration over which infants and young children can recall information increases steadily over the first 18 months of life (Greco et al., 1986; Hartshorn et al., 1998; Hill et al., 1988; Vander Linde et al., 1985). Using the VPC paradigm, Morgan and Hayne (2011) investigated whether this trend continues through to early childhood. In Experiment 1 of their study, 1-, 2-, and 3-year-old children were familiarized with one of the three cartoon faces for 10 s and were then tested either immediately or after a 24-h or 1-week delay. Consistent with Morgan and Hayne (2006b), 1-year-old children displayed a novelty preference when tested immediately, but not after the 24-h or 1-week delays. In contrast, 2-year-old children exhibited retention when tested immediately and after the 24-h delay, but not when tested after the 1-week delay; 3-year-old children exhibited retention across all delays. To test the limits of 3-year-old children's retention, a separate group was tested after a 1-month delay. After the 1-month delay, 3-year-olds did not display a novelty preference, suggesting that the limits of their retention on the VPC paradigm falls somewhere between 1 and 4 weeks. In Experiment 2 of their study, 4-year-old children were tested after the same delays as the 1-, 2-, and 3-year-old children, as well as after an additional 6-month delay. The 4-year-old children exhibited retention after all delays, including the 6-month delay. This sharp increase in retention between 3 and 4 years of age suggests that the linear increase in retention observed by Hartshorn et al. (1998) may not apply across all stages of development (**Figure 2**). Interestingly, the sharp increase in retention documented by Morgan and Hayne (2011) corresponds to the age at which many adults recall their first autobiographical memory.

Memory Retrieval

A large body of work has now shown that even once a memory has been forgotten, it can sometimes be restored by the presentation of a reminder (Campbell and Jaynes, 1966; Hartshorn and Rovee-Collier, 1997; Rovee-Collier et al., 1980; Spear and Parsons, 1976). For example, in the seminal demonstration of reminding in infants, Rovee-Collier et al. (1980) trained

Figure 2 The performance of 1-, 2-, 3-, and 4-year-old children on the VPC paradigm as a function of delay.

3-month-old infants in the mobile conjugate reinforcement paradigm and tested them after a 13- or 27-day delay – retention intervals after which 3-month-olds typically fail to exhibit retention. Twenty-four hours prior to testing, infants were presented with a reminder consisting of a 3-min exposure to the training mobile. Importantly, during the reminder, the mobile was controlled by the experimenter rather than the infant, precluding the opportunity for any retraining during the reminder treatment. During the retention test, the infants in both the 13- and 27-day delay conditions exhibited excellent retention; in fact, their performance was virtually identical to that seen immediately following the conclusion of training 2–4 weeks earlier, clearly demonstrating that forgotten memories can be retrieved and expressed under the appropriate circumstances.

Extending the work previously conducted with young infants, Morgan and Hayne (2006a) assessed the effectiveness of a reminder treatment on retention by 1- and 2-year-old children using the VPC paradigm. In their initial experiments, children were assigned to a reminder group or one of three control groups: forgetting control, encoding control, or reminder control. Children in the reminder group received a 10-s familiarization period followed by a 1-week delay, a delay after which children in both age groups typically fail to show a novelty preference (Morgan and Hayne, 2006b, 2011). After the delay, children in the reminder condition received a brief reminder, consisting of a 1-s presentation of the familiarized stimulus, immediately followed by the test. Children in the forgetting control group received the same familiarization and test as children in the reminder condition, but did not receive the reminder treatment prior to testing. Children in the encoding control condition were tested immediately after familiarization (i.e., they did not experience a delay) and children in the reminder control condition received only the reminder treatment and test (i.e., they did not experience the initial 10-s familiarization period).

Consistent with prior research, 10 s was sufficient for 1- and 2-year-olds to encode the target stimulus, that is, children in the encoding control condition exhibited retention when they were tested immediately after familiarization. Also consistent with prior research, following a 10-s familiarization period, 1- and 2-year-old children exhibited forgetting after a 1-week delay, that is, children in the forgetting control condition did not exhibit a novelty preference during the test. In addition, exposure to the reminder alone, in the absence of prior familiarization yielded no evidence of memory during the test, that is, children in the reminder control condition did not display a novelty preference. With respect to the reminder condition, 2-year-old children exhibited a significant novelty preference after the 1-week delay, demonstrating that the brief reminder was sufficient to reactivate the forgotten memory. Although 1-year-old children did not exhibit retention under these familiarization and reminding conditions, they did exhibit retention if the duration of the original familiarization period or the duration of the reminder was increased.

Prior research has shown that while younger infants require the re-presentation of the original experimental stimuli or the original context in order for memory retrieval to be initiated (e.g., Morgan and Hayne, 2006a; Rovee-Collier et al., 1980), older children can exploit retrieval cues that are different from those they originally encountered (e.g., Hayne et al., 2000; Herbert and Hayne, 2000). This increased flexibility in memory retrieval allows older children (and adults) to access and use their memories under conditions that are different from those under which the memory was originally encoded. In addition to physical reminders such as objects and contexts that were part of the original event, verbal reminders are also powerful retrieval cues. When during development can children begin to exploit verbal retrieval cues to reactivate their forgotten memories? In the first study designed to address this question, Morgan and Hayne (2007) assessed the effect of verbal reminders on memory reactivation in young children. In their study, separate groups of 4-year-old children received a 5-s familiarization period in the VPC paradigm followed by a 2-week delay. Utilizing the method developed by Morgan and Hayne (2006a), children in the nonverbal reminder group were reexposed to the

familiarization stimulus for 1 s prior to testing. Children in the verbal reminder group received the same familiarization time and were tested after the same delay, but before entering the experimental room, they were provided with the following reminder: "*Can you remember coming here two weeks ago?*" followed by "*Can you remember what face you saw last time you came?*" Consistent with the previous study, forgetting, encoding, and reminder control conditions were also included.

Children in both the nonverbal and verbal reminder conditions displayed a significant novelty preference during the test. In addition, there was no difference in the degree of novelty preference displayed by the nonverbal and verbal reminder groups suggesting that at least at 4 years of age, verbal and nonverbal reminders are equally effective in reactivating the forgotten memory. To investigate whether there were age-related changes in children's ability to utilize verbal reminders, Imuta et al. (2013) tested 2-, 3-, and 4-year-old children using a paradigm comparable to that used by Morgan and Hayne (2007). Replicating Morgan and Hayne's (2007) finding, 4-year-old children displayed a significant novelty preference following the presentation of the verbal reminder. Furthermore, both the 2- and 3-year-old children displayed a significant novelty preference following the presentation of the verbal reminder (Imuta et al., 2013). This finding suggests that by at least 2 years of age, children can use another person's verbal cue to reactivate a forgotten memory.

The research reviewed thus far demonstrates that recognition memory continues to develop throughout early childhood. Although recognition memory is a critical component of the explicit memory system, it is just one form of explicit memory subserved by the hippocampus. Indeed, recent neurophysiological evidence suggests that the emergence and development of recognition memory, like other hippocampus-dependent memory processes, depends on the maturation of specific circuits within the hippocampus (Brun et al., 2002; Lavenex and Lavenex, 2013). The maturation of each individual circuit, and the emergence of their respective memory processes, culminates in the emergence of episodic memory (Brun et al., 2002; Lavenex and Lavenex, 2013). With respect to infantile amnesia, this developmental sequence is important because it demonstrates that the explicit memory system can be functional during early childhood, yet still be unable to support the formation and long-term retention of episodic memories. Because episodic memory is the type of memory on which our autobiography is built, the next section reviews its emergence and development during early childhood.

The Emergence of Episodic Memory

The term episodic memory was coined by Tulving (1972) and was originally defined solely in terms of the spatial (i.e., where) and temporal (i.e., when) components of an event (i.e., what). In order to capture the autobiographical nature of episodic memory, Tulving (1985) added the notion of autonoetic consciousness, a consciousness that endows one with the knowledge that what one remembers is a personal past episode rather than something one simply has information about (i.e., noetic knowledge). Obviously, defining episodic memory by the conscious experience of remembering, rather than the content (i.e., what, where, and when), presents a challenge for testing the construct in young children, whose verbal skills are still limited. To overcome this verbal obstacle, Tulving (2005) devised the 'spoon test.' The spoon test derives from an Estonian children's story, in which a little girl dreams about attending a friend's birthday party. Guests at the party are served the girl's favorite dessert; unbeknownst to the little girl, however, guests were required to bring their own spoon. Because she does not have a spoon, the little girl must stand by and watch as others enjoy the dessert. The next night, before going to bed, the girl tucks a spoon underneath her pillow, just in case she returns to the party in her dreams. According to Tulving (2005), placing the spoon underneath her pillow provides nonverbal evidence of the girl's autonoetic consciousness.

To investigate the emergence of episodic memory, Scarf et al. (2013) tested 3- and 4-year-old children on a novel spoon test. Children participated in two sessions separated by a delay. In Session 1, children were taken out to a sandbox and were told, "I saw a pirate around here earlier today and I think that he might have hidden his treasure in our sandbox. Can you help me find it?" The experimenter and the child then dug up a treasure chest only to find that it was locked. The experimenter then asked the child if he or she had a key and, when the child said no, the experimenter suggested that they go back inside. Twenty-four hours later, the child returned to the laboratory and was told that they were going to go back out to the sandbox but, before they went outside, they were allowed to choose one of three objects: a brightly colored ball, a key, and a brightly colored wind-up toy. The critical measure was whether children would correctly pick the key to take with them.

Of the 4-year-old children, 75% selected the key, a proportion significantly above chance (1 in 3, 33%). In contrast, the 3-year-old children performed at chance, with only 33% selecting the key. There are two possible reasons why the 3-year-old children failed to select the key. One possibility is that the single trial did not provide the 3-year-old children with enough time to encode the sandbox episode. A second possibility is that the 3-year-old children adequately encoded the sandbox episode, but that they failed to retain the memory across the delay. To determine the source of their difficulty, Scarf et al. (2013) tested separate groups of 3-year-old children either immediately after the sandbox episode or after a 15- or 30-min delay. Consistent with the view that 3-year-old children were able to encode the sandbox episode, when tested immediately, a significant number of 3-year-old children selected the key. Across the no-delay, 15-min delay, and 30-min delay conditions, there was a linear decrease in the proportion of children selecting the key such that at the 30-min delay, performance was at chance. This finding suggests that the source of difficulty for 3-year-old children on the spoon test is retaining the memory across significant delays. To test the limits of 4-year-old children's retention, a separate group was tested after a 1-week delay. Remarkably, 100% of the 4-year-old children selected the key after 1 week (**Figure 3**).

The fact that episodic memory emerges by 3 years of age, and that the long-term retention of explicit and episodic

Figure 3 The performance of 3- and 4-year-old children on the spoon test as a function of delay.

memories develops considerably between 3 and 4 years of age, accords well with the average age of most adult's earliest memories. It is important to note, however, that although the seeds of episodic memory are clearly sown between 3 and 4 years of age, there are also significant individual differences in adult's earliest memories, suggesting that just the emergence of episodic memory per se does not explain the phenomenon of childhood amnesia entirely. The most consistent individual differences in the age of adults' earliest memories have been documented in cross-cultural studies and they provide, perhaps, the best evidence that the conversations that children have with adults are a causal factor in the development of autobiographical memory (Fivush et al., 1995; Nelson, 1990, 1993; Pillemer and White, 1989). New Zealand has the unique privilege of being home to the culture with the earliest memories of any culture studied thus far (Hayne and MacDonald, 2003; MacDonald et al., 2000). Māori are the native population of New Zealand and, on average, their first memories date from a few months before their third birthday. In contrast, New Zealand European's earliest memories, consistent with other European populations (Mullen, 1994; Mullen and Yi, 1995; Wang, 2001, 2006a,b), date from approximately $3^1/_2$ years of age (Hayne and MacDonald, 2003; MacDonald et al., 2000). The final section of this article explores how Māori cultural practices help adults encode and hold onto their earliest childhood memories.

Ngā Pūmahara o Ngā Tamarikitanga

The title of this section, *Ngā Pūmahara o Ngā Tamarikitanga*, is Māori for *Recollections of One's Childhood*. As noted above, Māori have the earliest memories of any culture studied to date, and this is a product of both how Māori parents recollect memories with their young children and also the types of memories they choose to recollect. Initial work comparing the way in which Māori and European New Zealand mothers talk to their children yielded the somewhat surprising finding that Māori mothers were less elaborative, when compared to New Zealand European mothers, when recollecting memories from the past (Hayne and MacDonald, 2003). Given the fact that Māori adults have significantly earlier memories than New Zealand European adults, this finding was inconsistent with work demonstrating that children of highly elaborative mothers generally have earlier first memories (Jack et al., 2009). From a cultural perspective, this finding was also surprising given that the Māori culture is renowned for its strong oral traditions and that their *whakapapa*, the oral transmission of family ancestry, is viewed as one of the richest in the world (Biggs, 1970).

One potential explanation for Hayne and MacDonald's (2003) finding is that the types of past events the parents were asked to talk about in the course of the research – recent events both the mother and child engaged in – were not representative of the types of events Māori parents generally talk about with their children. To investigate this possibility, Reese et al. (2008) compared Māori and New Zealand European mothers' elaborative style when they talked to their child about the child's birth and about a recent past event. Consistent with Hayne and MacDonald (2003), when discussing recent past events, New Zealand European mothers were more elaborative than Māori mothers. In contrast, when talking about the child's birth, Māori mothers were more elaborative, although only marginally so. Given that Māori and New Zealand European mothers are comparable in their general level of elaboration, another influence on Māori children's autobiographical memory development may be the content of their mother's elaborations. With respect to content, Reese et al. (2008) found that Māori and New Zealand European mothers talked with equal frequency about the people, places, and specific times of events, but that Māori mothers made more references to relative time and to internal states. Reference to

relative time and internal states may be especially important in children's autobiographical memory development. Young children have a great deal of difficulty with concepts of time, and the ability to organize episodic memories continues to develop well into early adolescence (Chen et al., 2013; Friedman, 2003). The use of relative time may help young children learn the chronological nature of autobiographical memory before they are able to master temporal concepts and it may also foster the ability to appreciate the order of events in individual episodic memories.

With respect to Māori mothers' references to internal states, outside of autobiographical memory development, there is a large body of work demonstrating that parent talk about mental states relates to young children's language and emotion understanding (e.g., Taumoepeau and Ruffman, 2006, 2008). Similarly, by referencing internal states, Māori mothers may contribute to children's developing sense of self. A sense of self is critical for both episodic and autobiographical memory, because it endows children with autonoetic awareness, allowing them to distinguish between memories they personally experienced (i.e., autonoetic) and those they did not (i.e., noetic). Although these accounts are speculative, in the absence of significantly greater levels of elaboration, the language used by Māori mothers when recollecting with their children, provides another potential explanation for Māori adults early autobiographical memories.

Summary

This article opened with a quote from T.S. Eliot's (1943) *Little Gidding* and it shall be ended on the same note. This article builds on earlier reviews by Rovee-Collier (1997) and Hayne (2004), providing an updated view on the current status of memory research in developmental psychology. Although empirical evidence for the principles of explicit memory development, the emergence of episodic memory, and the development of autobiographical memory has built over the past decade, the basic theoretical views have remained largely unchanged. With respect to the phenomenon of childhood amnesia, recent empirical work is providing us with a more fine-grained analysis of the phenomenon and how early theories may be integrated to provide a complete developmental account. In this context, T.S. Eliot's (1943) quote seems appropriate – the theories of childhood amnesia may not change, but each new finding makes the theories seem anew and in need of further exploration.

> We shall not cease from exploration
> And the end of all our exploring
> Will be to arrive where we started
> And know the place for the first time.
> T.S. Eliot (1943)

Memory in the Bee

Randolf Menzel, Institut für Biologie, Freie Universität Berlin, Germany

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Honeybees contradict the notion that insects elicit relatively inflexible, stereotypical behaviors. Their social life, navigation skills, symboliclike communication, rich learning repertoire, and dynamic forms of memory are embodied in a brain containing only one million neurons. Elemental and nonelemental forms of associative learning allow for context-dependent forms of learning, concept formation, and rule extraction. Neural plasticity correlating with learning can be traced to single identified neurons and small neural nets. Memory is formed by five sequential and parallel phases that are linked by specific forms of consolidation.

Navigation and Communication in a Social Insect, The Honeybee

The social life of the honeybee colony forms the evolutionary framework for the individual animal's behavior and is crucial for the survival of each bee (von Frisch 1967; Lindauer 1967). Social bees are exposed to a large and unpredictable range of environmental conditions and thus learning plays an important role both in the social context and in individual adaptations. The location of the nest site needs to be learned relative to landmarks within the reference frame of the sun compass. Changes to the society's conditions have to be recognized and used to control individual behavior. Communication about potential nest sites and food, water, and resin resources involve transmitting symbolic signals indicating distance and direction to the location of the respective object. The behavioral routine of communication, called the waggle dance, is performed in the dark on the vertical comb and encodes direction to the location as measured during outbound flights relative to the sun azimuth in the movement of the waggle phase relative to gravity. Distance as measured visually during flight is encoded in the speed with which the dance rounds are performed. The following bees (recruits) learn about the location and the quality of the respective resource and apply this information on their outbound search flights. Since they integrate dance communicated information into their navigation memory of the environment and perform novel short cutting flights between experienced and communicated locations, it is concluded that their spatial memory has the structure of a cognitive map (Menzel et al., 2011).

Learning

Learning Under Natural Conditions

Most studies of learning and memory formation in bees have focused on operant learning in the context of food collection. When a searching bee discovers a source of sucrose solution (under natural conditions; nectar), it quickly learns to associate the surrounding visual and olfactory signals with the reward. Acquisition functions indicate that olfactory stimuli (e.g., floral odorants) are learned within one or two learning trials, colors within one to five learning trials, and black-and-white patterns from the fifth learning trial onward (Menzel, 1985). Multiple learning paradigms have been studied under such conditions. Reversal learning, overlearning, and multireversal learning are effective learning phenomena in the bee. Reward schedules (e.g., continuous, fixed-ratio, and fixed-interval reinforcement schedules) are learned well. Additional operant learning phenomena have been studied in the tradition of experimental psychology and are reported by Bitterman (1988).

Visual categorization has been studied in free-flying honeybees trained to different visual stimuli, e.g., pattern orientation or bilateral symmetry. Bees choose the appropriate patterns despite the novelty of the structural details. The cases of categorical learning studied so far (orientation and bilateral symmetry of patterns) have been interpreted to demonstrate that bees focus their attention on a *single feature at a time* (orientation or bilateral symmetry) to solve the problem. However, Stach et al. (2004) and Zhang et al. (2004) showed that bees not only focus on a single feature but also assemble different features to build a generic pattern representation, which could be used to respond appropriately to novel stimuli sharing such a basic layout. These results show that honeybees extract regularities in their visual environment and establish correspondences among correlated features such that they generate a large set of object descriptions from a finite set of elements. The authors suggest that configurational properties of the figures, in which specific features such as circular symmetry, angular periodicity, bilateral symmetry, and the presence of a horizontal, high-contrast edge, the horizon, are integrated, could help the bees to classify the different stimuli.

Rule learning presupposes positive transfer of an appropriate response from a known set to a novel set of stimuli. One example is the detection of sameness and of difference. These rules are uncovered through delayed-matching-to-sample (DMTS) and the delayed-non-matching-to-sample (DNMTS) experiments, respectively. DMTS and DNMTS are paradigms frequently used to characterize working memory. Honeybees foraging in a Y-maze learn both rules when trained to either pairs of colors or patterns (Giurfa et al., 2001). Bees trained with colors and presented in transfer tests with gratings that they have not experienced before solve the problem and choose the grating identical to the sample at the entrance to

the maze. Similarly, bees trained with the gratings and tested with colors in transfer tests also solve the problem and choose the novel colors corresponding to those of the sample grating at the maze entrance. Working memory for the sample underlying solving a DMTS task is around 5 s (Zhang et al., 2005). Moreover, bees trained in a DMTS task can learn to pay attention to one of two different samples presented successively in a flight tunnel (either to the first or to the second) and can transfer the learning of this sequence weight to novel samples (Zhang et al., 2005).

Contextual learning is a term widely used for describing conditional discrimination, which can be subsumed in several cases of the so-called occasion setting problem. In these conditions, a given stimulus, the occasion setter, informs the animal about the outcome of its choice. For example, bees were trained to fly to two feeding stations, one in the morning and one in the afternoon. Thus, depending on the time of day, bees flew in one direction or the other, showing that temporal information can act as the occasion setter for a sensory-motor routine. Olfactory cues can also act as occasion setters for the choice of appropriate navigation vectors. Bees trained to forage at two feeders, placed at different outdoor locations and carrying different scents, recall the locations of these food sites and fly to them when the respective scent was blown into the hive. These results indicate that familiar scents can trigger navigational memories in order to define appropriate context-dependent responses.

Classical conditioning of innate responses is a most convenient way to study the behavioral and neural mechanisms of associative learning. In hungry honeybees, a sucrose stimulus at the antennae reliably releases the extension of its proboscis (PER: proboscis extension response). Conditioning to olfactory or mechanical stimuli as a conditioned stimuli (CS) is very effective (Menzel and Giurfa, 2001). The associative nature of PER conditioning was established by demonstrating that only forward pairing of CS–unconditioned stimuli (US) sequences is effective, by various control groups (unpaired CS and US, CS- or US-only presentations), and by differential conditioning of the two olfactory stimuli (Bitterman et al., 1983). The predictive value of the CS depends on the reliability with which it is causally related to the US. In differential conditioning, the reversal to the initially unpaired stimulus is slower after more frequent unreinforced preexposures than after a lesser number of preexposures. Overshadowing and blocking experiments are used to characterize the informational content of the CS. It was concluded that attentiveness is not a limiting factor, and that the salience or associability of a stimulus is indeed an important factor.

In studies of nonelemental learning, paradigms have been developed for which the associative strength of a specific event, stimulus or reaction, is ambiguous and therefore cannot be predictive for solving a problem. In the honeybee, several recent studies have addressed the issue of elemental vs nonelemental learning, using visual training of free-flying animals or olfactory conditioning of harnessed animals. In both modalities, bees are able to solve a biconditional discrimination (AB+, CD+, AC−, BD−). This capacity demonstrates that both visual and olfactory compounds are learned under certain circumstances as entities different from the simple sum of their elements. Similarly, negative patterning experiments (A+, B+, AB−) have also been performed in both the visual and the olfactory modality. Such discrimination can only be explained if the compound AB is treated as being different from the simple sum of its elements. The results are interpreted according to a modified unique cue hypothesis (Lachnit et al., 2004).

Neural Correlates of Learning and Memory Formation

The neural correlates of learning and memory in bees can be traced to particular regions of the brain, and in some exceptional cases to unique identified neurons. Recording these neural correlates is possible under conditions when the animal associates an odor with sucrose reward and retrieves the memory later (PER conditioning paradigm, see above). This form of Pavlovian classical conditioning is a robust learning phenomenon of bees that are constraint to a holder and the brain is exposed to intra or extracellular recordings, Ca^{2+} imaging and manipulation of molecular targets.

Insect brains are rather small and equipped with neurons that are at least partially identifiable at the single-neuron level. The honeybee brain has a volume of about 1 mm^3 and contains approximately 950 000 neurons which are organized in well-structured neuropils. The small size of the brain allows to fully reconstruct in 3D the spatial arrangement of the neuropils with the resolution of the light microscope and to incorporate the connectivity of neural nets into a virtual atlas of the brain (http://www.neurobiologie.fu-berlin.de/beebrain). An essential structure for associative olfactory learning and memory storage is the paired mushroom body (MB). The MB is a high order integration site where processed sensory inputs of all modalities converge. Using the olfactory PER conditioning paradigm it was shown that the memory trace is distributed across the olfactory pathway involving the antennal lobes (AL) and the MB. Reversible blocking of neural activity in the AL and the MB after a single olfactory learning trial indicated that the AL contributes to the consolidation of a memory trace only during the first 1–2 min after a single conditioning trial, and the MB over a period of up to 10 min. Furthermore, it was found that blocking neural activity in the AL could prevent formation of olfactory memory, but applying the same procedure to the MB could block memory formation only partially indicating that consolidation to lasting memory is distributed between these two neuropils and involves different time-dependent processes. Additional information about the localization and dynamic of the respective memory traces come from manipulation of cellular processes and recordings of neural activity (see below).

Neural substrates of learning and memory are expected to be related to plasticity of neural functions, and the search for such plasticity should ideally be performed on the single-neuron level under conditions when the animal learns, consolidates memory and retrieves it. For such measurements, intra and extracellular recordings have been successfully used to monitor neural processes during learning and memory retrieval at the single-neuron level. In two cases, the ventral unpaired median neuron 1 of the maxilary neuromere

(VUM_{mx1}) neuron and the pedunculus extrinsic neuron 1 (PE1) neuron in the bee brain, has it been possible to return to the same individual neuron in subsequent recordings from different animals exposed to associative learning schedules.

A particularly striking neuron in the bee brain is VUM_{mx1}, which was shown to serve the function of a value system (Hammer, 1993). Activity in this neuron constitutes the neuronal representation of the food reward in appetitive associative olfactory learning. Behavioral learning of an olfactory stimulus can be induced by substituting the sucrose reward in PER conditioning by an artificial depolarization of VUM_{mx1} immediately after olfactory stimulation (forward pairing). If depolarization precedes olfactory stimulation (backward pairing) no learning is observed. The same forward–backward effect is seen when sucrose is used as the reward under similar experimental conditions. Thus VUM_{mx1} constitutes the neural correlate of the US in associative olfactory learning.

Intracellular recording of VUM_{mx1} during differential conditioning to two odors, a forward-paired one (CS+), and a backward-paired one (CS−), leads to an enhanced response of VUM_{mx1} to CS+ and to an inhibitory response to CS−. Thus VUM_{mx1} learns about the forward-paired odor, a fact that can support second-odor conditioning, blocking, and the phenomena involved in reconsolidation (see below). The response of VUM_{mx1} to an expected reward is strongly reduced, and even inhibited during sucrose stimulation. The response to sucrose after CS− (no reward expected) remains normal. These properties provide the neural circuitry with an error signal for learning similar to what was found for dopamine neurons of the basal ganglion in the mammalian brain (Schultz, 2006).

It is yet unknown whether VUM_{mx1} itself or the other 14 identified VUM neurons of the subesophageal ganglion belong to a general modulatory pathway, which may also serve non-associative forms of plasticity and arousal. Furthermore, since VUM_{mx1} converges only with the olfactory pathway and not with other sensory pathways in the bee brain, it may be the specialized reward system for olfactory cues, and other value systems may exist for visual and other forms of learning.

A second single identified neuron with learning related plasticity is the PE1. PE1 reduces selectively its responses to CS+ during odor conditioning. PE1 receives predominantly excitatory input from Kenyon cells (MB intrinsic neurons) across the whole peduncle. Inhibitory input to PE1 can be traced to side branches of GABA-ir profiles of the protocerebral calycal tract (PCT) (Okada et al., 2007). PCT neurons both enhance or reduce their responses to the learned odor. It is concluded that PE1 receives input from the subpopulation of PCT neurons that express learning related enhancement providing an example of associative plasticity on the network level as a correlate of learning. Ultimately memory traces have to be localized in neural nets, and this is accomplished by Ca^{2+} imaging approaches, which also allow to identify the contributing neurons. Olfactory memory traces were localized both in the AL and the MB by Ca^{2+} imaging (Szyszka et al., 2008). It will be the task for future research to identify the populations of synapses, their distributions, and associative properties that contribute to the different forms of memory in the bee brain.

Memory

Even an insect with such a little brain consolidates memory via several sequential and parallel processes, recalls memory from different stores, and organizes memory according to the behavioral needs. In this respect its memory structures resembles features that can be considered to reflect basic components of memory formation and retrieval.

Sequential Memory Processing

A stable, lifelong memory is formed after even only a few learning trials in free-flying bees (Menzel, 1999). The retention curve after a single learning trial follows a biphasic time course, which indicates that memory and retrieval is at first very high, fades to a minimum 2–3 min after learning, rises again within the following 20 min, and stays high for a number of hours; this is true both in PER conditioning and for free-flying bees. The early memory phase in the minutes range is particularly susceptible to both extinction and reversal learning, whereas the consolidated memory is much more resistant. The sensitizing effect of the appetitive stimulus overlaps with the early high response level, indicating that, at least in PER conditioning, the nonassociative memory initiated by the US contributes substantially to the response probability immediately after the single learning trial. Amnestic treatments (cooling, narcosis, weak electroconvulsive brain stimulation), if applied within 2–3 min after the single-trial learning, erase the memory trace, indicating a susceptible short-term memory (STM). The memory initiated by a single conditioning trial consolidates within a few minutes so that it becomes resistant to retrograde amnestic treatments. The time course of retrograde amnestic sensitivity is independent of the kind of learning (operant color learning, olfactory PER conditioning), but depends on the particular structure of the brain where the treatment is applied. Several conditioning trials within STM make the memory trace immune to amnestic treatment.

Several forms of longer-lasting memory have been discerned on the basis of behavioral, biochemical, and pharmacological experiments performed with olfactory PER conditioning. The respective time courses and transitions between five forms of memory have been related to the temporal sequence during the foraging cycle. (1) Associative induction and early short-term memory (eSTM): eSTM covers the time window during which foraging bees can expect to be exposed to the same stimuli, since flowers most frequently occur in patches. No specific choices need to be performed at this time, and general arousal (depending on the strength of the US) will suffice to control whether the animal stays in the patch or postpones choices for a later time. (2) Late short-term memory (lSTM): the transition to the selective associative memory trace during lSTM is a rather slow process after a single learning trial lasting up to several minutes, and happens very quickly after multiple learning trials. Thus consolidation is both time- and event-dependent, where events have to be associative experiences and not just CS or US repetitions. The behavioral relevance of these findings for foraging behavior has been related to the temporal separation between intra and interpatch visits. (3) Midterm memory (MTM): at the beginning of MTM, behavior is controlled by consolidated, highly specific memory. At this stage, memory is more resistant to

extinction, conflicting information and elapsing time, and some information about the context dependencies may have already been stored. Under natural conditions bees have usually returned to the hive and departed on a new foraging bout within the time window of MTM. (4) Early long-term memory, and (5) late long-term memory: LTM requires multiple learning trials, indicating that specific information, which can be extracted only from multiple experiences (signal reliability, context dependence) controls the transfer to LTM.

Processes of memory consolidation bridge the five different forms of memory phases, and these processes can be partially interpreted on the level of cellular and neural events. Most information exists for olfactory reward conditioning in harnessed bees (Menzel et al., 2007).

Associative Induction and Early Short-Term Memory (eSTM)

An associative learning trial leads to associative induction and eSTM in the range of seconds. This memory is initially localized in the primary sensory neuropil, the antennal lobe, and is highly dominated by appetitive arousal and sensitization induced by the US: sucrose. Thus eSTM is restricted to the first synaptic connections in the sensory pathway. It is rather unspecific and imprecise. The associative component, which connects specific stimuli with motor actions, already exists at a low level, and develops later over a period of several minutes.

At the cellular level, stimulus association is reflected in the convergence of excitation of the pathways for the CS and the US. There are three neuroanatomical convergence sites of these pathways (the antennal lobe, AL, the lip region of the mushroom bodies, MB, and the lateral protocerebrum). Two of these sites can independently form an associative memory trace for an odor stimulus. The dynamics of these two traces are different: the AL establishes the trace quickly, the MB stepwise by a consolidation process in the range of minutes during the transition to a late form of STM (lSTM). The molecular substrates for the formation of the associative links are unknown. Neither a glutamate receptor, as shown for the hippocampus, nor adenylylcyclase, as proposed for *Aplysia*, appear to play a role in the bee. However, cyclic adenosine monophosphate (cAMP) upregulation of protein kinase A (PKA) during STM is necessary for memory transition to MTM and long-term memory (LTM), and an increase in PKA activity is specifically connected with associative trials, indicating PKA's role in consolidation to lasting memories established during consolidation (Müller, 2012).

Late Short-Term Memory (lSTM)

The transition to the associative memory trace during lSTM is a rather slow process after a single learning trial lasting up to several minutes, and a quick one after multiple learning trials. Thus, consolidation is both time- and event-dependent, where events must be associative experiences and not just CS or US repetitions. The MB appear to be selectively involved.

Midterm Memory (MTM)

MTM is physiologically characterized by a wave of protease-dependent protein kinase C (PKC) activity in the antennal lobe. It might be, therefore, that the primary sensory neuropil is a substrate for MTM. Since the MB appear to be the critical substrate for consolidation during lSTM, it has been speculated that the MTM trace in the AL is established under the guidance of the MB. The MB provides the information that relates the memory traces in the primary sensory neuropils to context stimuli across modalities. Output neurons of the MB feedback to the AL.

Long-Term Memory (LTM)

Consolidation into lasting memory depends not only on PKA activity but also on NO synthase activity, indicating that both cAMP and cyclic guanosine monophosphate (cGMP) are important second messengers for consolidation. Indeed, activating cAMP dependent PKC in the antennal lobe after a single learning trial leads to stable LTM (Müller, 2000). LTM is divided into two forms, an early LTM (eLTM, 1–3 days) characterized by prolonged PKC activity and translation dependence, and late LTM (lLTM, >3 days) depending on transcription. The transition from lSTM to both forms of LTM appears to be independent of MTM, because inhibiting the characteristic substrate of MTM (protease-dependent enhancement of PKC activity) does not prevent eLTM and lLTM being formed.

Structural changes in the connectivity between neurons have been proposed as the substrates for LTM in vertebrates and invertebrates and are believed to be at least one target of the translation and transcription dependence of LTM formation. In bees, direct evidence for LTM-related structural changes is lacking, but measurements of MB subcompartment volume indicate that more experienced bees have bigger volumes and more elaborate dendrite branches.

Glutamate Transmission and Memory Formation

Glutamate is the major excitatory transmitter in mammals and plays a central role in neuronal plasticity in vertebrates. Its function in the insect brain, however, is only poorly understood. Glutamate receptors have been identified in honeybees, and manipulation of glutamate function using pharmacological tools and RNAi supports a function in memory consolidation processes (Mussig et al., 2010). Uncaging glutamate immediately after a single-trial training in the MB improves the formation of an LTM, and thus mimics the effect of a strong training protocol. Uncaging glutamate shortly before weak training has no effect, pointing to a defined function of glutamate with respect to memory processing rather than learning. This function of glutamate is restricted to the MB circuitry, since glutamate release in the AL does not improve learning or retention. Taken together, glutamate action appears to be restricted to the MBs, where it contributes to induction of LTM in a time window shortly after training. Although it is still unclear whether this late memory phase is mechanistically identical with the LTM induced by a strong training (three-trial conditioning), the findings provide an example for parallel molecular processes underlying learning and memory formation *in vivo* occurring in different neural circuits.

In summary, the bee brain of merely 1 mm^3 and a total of 950 000 neurons, establishes multiple and distributed memory traces not very different from mammalian memory in the general temporal dynamics, characteristics of contents,

and cellular substrates. It may thus serve as a suitable model for the study of memory structure and formation.

Reconsolidation

When memory is retrieved from a remote store by exposing the animal to the learned stimulus without reinforcement (extinction trial) two processes are initiated: extinction learning, due to the fact that the stimulus originally associated with reinforcement is now presented without it, and reminder learning, which may either recruit the original stable memory about the learned stimulus and bring it back into an unstable form, or it initiates a new learning trial based on the fact that a learned stimulus also activates the reward system and thus initiates new learning (see above). Both extinction and reminder learning are followed by their respective consolidation processes: consolidation of an extinction memory and reconsolidation of the reminder memory. In the honeybee the balance between the extinction and reminder learning processes and their respective consolidation processes depends on the number of extinction trials. Extinction learning is dominant after two extinction trials, whereas reminder learning is expressed in a recovery from extinction and is induced by many (e.g., five) extinction trials. Consolidation of reminder learning (reconsolidation) depends on protein synthesis, which indicates that a new learning process is going on, as shown in the vertebrate studies (Stollhoff et al., 2005).

The results on reconsolidation in the honeybee can be explained by reference to the properties of the reward system in the bee brain, and do not require the assumption that reconsolidation is based on processes by making the consolidated memory trace again sensitive to novel consolidation (Eisenhardt and Menzel, 2007). It was found that the reward neuron VUM_{mx1} (Hammer, 1993) not only codes for appetitive reinforcement of odors, but also learns to respond to the conditioned odor stimulus. An extinction trial indeed activates the VUM neuron. This means that an extinction trial will lead to new appetitive learning without an external reinforcing stimulus but through in internal reinforcement signal from the VUM neuron. The data confirm this interpretation: two forms of learning can be separated, one based on the lack of external reinforcement (extinction learning) and the other based on internal reinforcement (reminder learning). These conditions are best captured by the 'internal reinforcement hypothesis,' which states that the balance between extinction and reminder learning depends on the relative strength of the respective reinforcements. The balance will be shifted to the internal reinforcement with more unrewarded presentations of the learned stimulus.

Memory Models: Quantitative

Bennet Murdock, University of Toronto, Toronto, ON, Canada

© 2015 Elsevier Ltd. All rights reserved.

Abstract

After a brief introduction, a description is given of memory models, the information-processing view, and recent developments. Three specific memory models are discussed in greater detail: MINERVA, REM, and TODAM. The article ends with some applications to data and a look at other areas in the memory field.

Introduction

As has been said before, the study of learning and memory has a long history but a short past (empirically a long history and theoretically a short past). What many people do not realize is that over the last 150 years of research there has been a steady accumulation of data in the area of human learning and memory. Many years ago a physiological psychologist confided to me that our data was better (more reliable and robust) then his. This may have been a slight exaggeration, maybe he was only being polite, or maybe things have changed in the interim. Whatever, we have the right to be proud of our data.

The models or theory are another matter. We are relative novices in this area, and although many models can give accurate fits to selected data sets, they are not always as broad as they could be and the level of mathematical sophistication is not too high. However, this is gradually improving and the nature of the modeling seems to be changing from formal 'hypothetico-deductive' models (Hull, 1943) to computer-simulation models (Simon and Feigenbaum, 1964), and it can be argued that this is the more appropriate method to understand the wide variability that is perhaps the outstanding characteristic of human memory.

There are a number of 'textbooks' of human memory, research monographs that describe in breadth and depth the state of the field at the time they were written. My favorite examples are McGeoch (1932), Osgood (1953), Crowder (1976), Murdock (1962), Neath and Suprenant (2002), and Kahana and Caplan (2002). Introductory psychology textbooks (of which there are many) only begin to scratch the surface, giving you bit of the terminology and a few of the major empirical results, but they are usually quite superficial when it comes to models and theories.

This article is about quantitative memory models, and I can assure the reader that most of the experimental data analyzed in these memory models has stood the test of time. However, the models are more recent and constantly being revised. This should not bother the reader; Newton's model was quite useful until Einstein came along, and sometimes early versions of a model turn out to be just special cases of a more general model.

The memory models to be covered here fall into four categories corresponding to four different types of memory tasks: item recognition, paired associates, serial-order effects, and free recall. To make the models more comprehensible I will briefly explain what is involved in each of these four tasks. This is necessary because often the models are task specific; they only apply (rigorously) to one type of task, though of course they may generalize. In studies of item recognition the experimenter presents a list of items (words, pictures, whatever) to the subject(s) and then tests with old and new examples. Some items in the test list are 'old' (i.e., presented in the list) and some are 'new' (i.e., not presented in the list). With a yes-no procedure, all the subject has to say when a test list containing a mixture or old and new items is presented is 'old' or 'new,' but often a confidence judgment is used where the subject also has to indicate on some scale how confident he or she is. This scale can be one to three, one to five, one to ten, or whatever the experimenter chooses, but the range is seldom more than ten.

In studies of paired associates, lists of pairs (A–B, C–D, E–F, and so on) are shown (visual or auditory presentation) to the subject and then, usually in a scrambled order, each pair is tested in a random order one by one, usually in a forward order (C–?, A–?, F–?) or in some experiments in a backward order (D–?, B–?). There can be a single presentation (i.e., study then test) for one trial or 'short-term' or multiple presentations perhaps for a fixed number of trials or perhaps until some criterion (e.g., 75%; 100%, two consecutive perfect trials) is reached. This is testing recall. The first or second item in each pair is presented to the subject, who must then recall its mate (second or first item, respectively).

Sometimes with this paired-associate method pair recognition is tested. 'Intact' (e.g., C–D) or 'rearranged' (E–B) pairs are used in the test phase, and the subject has to say either 'old' or 'new.' This old–new judgment may be supplemented with confidence judgments. Either way (recall or recognition), there is only a single list. This 'single-list,' procedure is often extended to studies of pairs of related lists. These related lists may test for 'retroactive' or 'proactive' interference (Crowder, 1976). Retroactive interference (RI) can be symbolized by an A–B, A–C arrangement (first member same in the two lists, second member different), while proactive interference (PI) can be symbolized as A–B, C–B, so that the first member is different but the second member is the same. Thirty years of research under the aegis of interference theory (Crowder, 1976) was devoted to this topic (main effects and similarities and differences between RI and PI), and although the data are still as reliable as ever, interference theory has been incorporated into formal memory models and will not be discussed further.

In serial learning, a list of items (common words, nonsense syllables, poetry) is learned trial by trial, either with a study-test

 http://dx.doi.org/10.1016/B978-0-08-097086-8.43065-5

procedure or the method of anticipation. If the former is used, the entire list is presented and then recalled as best is possible, and this is repeated until some criterion is reached. In the method of anticipation, each item is presented and the subject is to anticipate what the next item will be. The next item is shown, and so on, trial after trial, until some learning criterion is reached. The dependent variable (measure of learning) is usually the number of trials to some criterion (all correct, some fraction, or some number of successive correct trials). This is the learning paradigm used by Ebbinghaus in his pioneering study of learning and memory (Ebbinghaus, 1913/1964). Free recall will be presented shortly.

Models

Formal (quantitative) memory models probably started with the Ebbinghaus forgetting curve. He summarized the results of an extensive set of experiments on serial learning, where he was both subject and experimenter, with what we would now call an exponential decay curve showing rapid forgetting at first and progressively slower forgetting as time passed. It was exponential because the rate of forgetting was roughly inversely proportional to the time passed between learning and test. This exponential forgetting curve may well have been the first formal quantitative description of forgetting.

After Ebbinghaus, serial learning was '*de rigueur*' in the early 1900s. It was to human learning and forgetting what maze learning was in rats. The emphasis in both cases was on accurate description of the learning or forgetting curves, and although it can be disparaged as mere 'curve fitting,' at least it was a start. These studies provided the data base for McGeoch's influential book on learning and memory (McGeoch, 1946), and this is probably where a theoretical dispute broke out. There were 'decay theorists' and 'interference theorists,' and McGeoch epitomized the interference point of view by stating 'iron rusts in time but the cause is oxidation.'

American psychologists took note and the 'interference' banner was carried by Benton Underwood at Northwestern University and Leo Postman at UC Berkeley. Their view of memory was the prevailing view until the early 1970s (Postman and Underwood, 1973). However, British psychologists held staunchly to the decay point of view with a rather more creative approach (see Bartlett's *War of the Ghosts*). Neither of these could be considered quantitative models of memory by any stretch of the imagination.

Then a fourth memory/learning paradigm appeared: free recall (Bousfield, 1953). This task was less structured then item recognition, paired associates, or serial-order learning. The task was simplicity itself: the experimenter would present a list of items (usually words) of some list length and at some presentation rate and ask the subject to recall as many items as possible in any order. Single-trial free recall was of course only one trial; free-recall 'learning' involved repeating the study list over again to the subject always in the same order with recall after each presentation, and this could be done for a fixed number of trials or until some criterion (one perfect, two consecutive perfect, etc.) was reached.

This method was popularized by Deese (1959), but the results of a more elaborate study by Murdock (1962) turned out to be quite influential. The results showed a brief (three-item) primacy effect, a more extensive (seven-item or so) recency effect, and a level asymptote connecting the two. The primacy and recency effect were essentially independent of list length (10, 15, or 20 words) and presentation rate ($2\ s^{-1}$, $1\ s^{-1}$, or 1 per 2 s), but the asymptote was approximately proportional to the total presentation time. The results could be characterized by a Gompertz double-exponential function. These results generated considerable interest in memory modelers, so much so that they were included along with the results from a short-term probe test as the two short-term memory data sets that any creditable model should be able to explain (Norman, 1970).

There is not space here to report all the data obtained from these four paradigms, or even a small subset. The interested reader is referred to Kahana and Caplan (2002) for the latest survey, but the reader should be warned that even his data presents only a small subset of all the data that have been reported in the literature in well over 100 years of research.

Information-Processing View

The next major step was probably an information-processing view (although it was not called that at the time), namely, Broadbent's (1958) Y-shaped tube. Broadbent considered the human information-processing system to be preceded by a 'limited-capacity' attentional system, which he characterized as a Y-shaped tube. Consider an experimental study of 'dichotic listening,' meaning that a subject was listening to two simultaneous streams of unrelated words presented over separate headphones to the two ears. That is, one stream was presented to the left ear and the other stream was presented to the right ear. Imagine the information from the two ears feeding into some hypothetical central processor that could map input into output or recall. Accuracy would depend upon how well this was done.

As it turned out, human performance (recall accuracy) was not too good, and if recall was delayed somewhat after the presentation ended, it was even worse. To explain these data, Broadbent expanded this metaphor to postulate that there was 'acid' in the tubes and if the information (conceived as metal balls resting in the tubes) stayed there too long before recall (which emptied the tubes), the acid would result in decay and performance (number of words recalled) would decrease. The Y-shaped tube metaphor was used to explain the fact that if the input streams to the two ears were reported sequentially, the channel reported second was always reported (recalled) less accurately than the channel reported first (Moray, 1959).

There is an important issue here. Long before Broadbent's work, 'decay' had been a popular notion in the study of human memory. Then the American psychologist John McGeoch took issue with the decay notion. The disagreement between McGeoch and Broadbent (interference vs decay) put American and British psychologists in opposing camps, and traces of this controversy still exist today.

Recent Developments

The dispute between interference and decay still goes on today but at a more sophisticated level. The big leap ahead in our

theoretical understanding occurred at Stanford University in the mid- to late 1960s under the aegis of the Institute for Mathematical Studies in the Social Sciences. Under the leadership of Professors William K. Estes and Patrick Suppes, there was a critical mass of very talented researchers and theorists, most notably and in alphabetical order, Richard Atkinson, Bob Bjork, Gordon Bower, Ed Crothers, James Greeno, Chizuko Izawa, Walter Kintsch, Steven Link, Richard Shiffrin, James Townsend, and Joe Young. Much of their early work was on the 'one-element model,' a Markov model for learning and memory. This model postulated all-or-none learning so a particular memory trace was in one of only two states: 'learned,' in which case it could be recalled, or 'unlearned,' in which case it could not be recalled. This one-element model had a short life; experiments by various members of this group (most notably Greeno, 1967) showed that this view of memory was untenable. Actually, there were some Gestalt-oriented psychologists (Rock, 1957) who did not give up easily and presented some experimental evidence supporting an all-or-none view, but it was not accompanied by any formal modeling attempt.

One remnant of this early work not only survived but became probably the single most widely quoted and influential quantitative memory model in the history of our field to date. This was the Atkinson and Shiffrin (1965) 'buffer model.' There is a rumor that one night Atkinson asked his graduate students over for an evening of beer and pretzels, and the agenda was to suggest how human memory might be like a computer. Computers (not laptops but mainframes and Digital Equipment Corporation laboratory computers such as the PDP-7 and the PDP-12) were starting to become popular, and maybe we could not only teach them to learn but also learn from them. The result is reputed to be the buffer model.

The buffer model assumed that (like a PDP-12) there was an accumulator (AC) or very small short-term memory and a 'multiplier/quotient' (MQ) that could use the data entry from the AC as 'grist for the mill' (i.e., number crunching or multiply and divide). The AC in the buffer model was a short-term limited capacity store that could hold a few items. The longer an item resided in this short-term store, the greater the chances that it would be transferred to a hypothetical long-term store. Thus there was a short-term memory (STM) and a long-term memory (LTM). This buffer model was basically a simulation model rather than an analytic model, although some explicit expressions were derived. It was able to explain or fit a large amount of experimental data (including the serial position effect of free recall, described earlier). By then the experimental literature had grown considerably since the time of Ebbinghaus and was highly reliable. A noted psychologist who worked with both physiological and psychological memory and learning data once told me that the human memory data were much more robust and reliable than the physiological data he had to work with. However, that was probably 30 years ago and the situation may have changed since then.

This buffer model was soon followed by a cognitive revolution at Stanford under the aegis of John Anderson, who was a graduate student working with Gordon Bower. An important component of this so-called 'cognitive revolution' was a book by Ulrich Neisser (Cognitive Psychology, 1967) that is still cited today. Important work was done both at Stanford and at Carnegie Mellon with Newall, Simon, and Shaw. After graduation from Stanford, John Anderson joined them and developed the Automatic Control of Thought (ACT) (Anderson et al., 1998). These models have been quite influential not only in psychology but also in education and the school system. They are a little off the beaten path that I am trying to follow and so they will not be discussed further here, but they should not be overlooked in any account of the development of our field.

The cognitive science approach (not ACT or ACT-R) received a body blow over the issue of 'catastrophic interference' in studies of retroactive inhibition (RI). As has been mentioned, there are two lists of paired associates to be learned. After the first A–B list has been learned then the second or A–D list has to be learned. Many experimental studies have shown that the second-list learning is gradual; slowly but surely the D responses of the second list replace the B responses of the first list. What happens in a connectionist model? As shown by Ratcliff (1990), the 'relearning' (A–D) list only takes a single trial or two. Thus connectionist models show 'catastrophic' (one- or two-trial) unlearning, which is quite different from what happens in experimental studies. Although there have been a few theoretically inspired attempts to provide a connectionist solution to this situation, the applecart had been overturned and connectionist theorists turned to other problems.

However, this does not mean that all interest in simulation models of memory was lost. Roughly at the same time, distributed (as opposed to localized) memory models appeared on the scene. The most widely tested were the Theory of Distributed Associative Memory (TODAM) model of Murdock (1983), after the Content Addressable Distributed Associative Memory (CADAM) model of Liepa (1977); MINERVA (Hintzman, 1984), named after the Greek goddess of poetry, medicine, wisdom, commerce, weaving, crafts, and magic; and the Search of Associative Memory (SAM) model (Gillund and Shiffrin, 1984). CADAM was really three models in one (for recognition, paired associates, and serial-order effects) whereas TODAM was a unified model that applied to all three.

CADAM/TODAM are simulation models while MINERVA/SAM are computational (analytic) models. CADAM/TODAM assume the underlying encoding/storage/retrieval processes, run the simulations, and calculate the predicted results from analyses of the simulated data. MINERVA/SAM make hypotheses about the underlying processes and mechanisms, derive analytic expressions from these assumptions, and then use these expressions to make predictions of the data. Rather than describe each model in detail, I will simply discuss their storage assumptions, retrieval assumptions, and response rules and try to give some indication of how they work. The predictions can be obtained mathematically from derivations or from computer simulation.

Overview

These memory models make different assumptions about encoding, storage, and retrieval, the three basic processes of short-term memory. CADAM/TODAM assume that features are represented by random samples from a normal distribution with mean zero and some variance. This assumption was used in the CADAM model by Liepa, who chose this assumption

because he told me that in quantum mechanics this assumption is standard, as it obviates the need for normalization later on. MINERVA assumes a ternary representation for the encoding of features, 1, 0, or −1, while SAM assumes a geometric representation. That is, each feature value is a random sample from a geometric distribution with some probability (p value). Features are encoded with probability p or not encoded with probability $(1 - p)$.

How are associations represented? In TODAM, an association is represented by the convolution of two A and B item vectors. Convolution ('Faltung' in German) is a particular way of combining two distributions; for details, see (Bracewell, 1965: Chapter 3). This convolution maintains the vector form so items and associations can be stored in a common memory vector. If circular convolution is used (Plate, 1995), items and associations are the same dimensionality. One can form a linear convolution by forming the outer product matrix and then summing the diagonals. A circular convolution can be formed by folding a linear convolution or using the Fourier transform directly (Bracewell, 1965).

In MINERVA, the A and B members of an A–B pair are simply concatenated and stacked end-to-end and zero denotes a missing or unknown feature. What about retrieval? In MINERVA, applying the probe (A item of an A–B pair or B member for backward associations) will retrieve the corresponding A member. Associative symmetry is guaranteed from the convolution-correlation identity (Murdock, 1983). This is important because there is strong evidence for associative symmetry; backward associations are as good as forward associations (Kahana and Caplan, 2002). In TODAM, associative symmetry is guaranteed because it follows from the convolution/correlation identity. So one way or another all three models can predict associative symmetry, and this seems to hold up in experimental situations.

In an experiment, subjects can recognize items that were or were not in the list of pairs (targets and lures, respectively). I do not know of any rigorous proofs of this, but suspect that even if this prediction does not flow naturally (as it does in TODAM), it would not be difficult for any of these models to predict associative symmetry. However, in TODAM all information is stored in a common memory store, so given the retrieval operation (correlation), the retrieved information is at best a noisy approximation to the target item. This approximation will vary with a number of factors (number of pairs in the list, number of features in each item vector, A and B item similarity both within and between). There are deblurring algorithms, that is, computational procedures that will find the best target (A or B item) for any A′ or B′ approximation (e.g., Hopfield, 1982). However, to my knowledge these have not been implemented in any of the models. Instead it is simply assumed that the best match will be the item retrieved, but how one goes from an approximation to the best match has not been specified.

MINERVA

Here is an account of how MINERVA (Hintzman, 1984) works in more detail. With stimulus presentation, the features of an item are from a short-term or 'primary' memory (PM) and copied to a long-term or 'secondary' memory (SM), and SM 'echoes' or returns a signal to PM; this is called 'echo intensity.' SM is a large collection of 'experiential records,' records of past experience. There are multiple copies in SM rather than 'stronger' copies of each individual experience.

When a probe goes to SM it is matched by all the SM traces and you get a 'summed similarity.' The resulting memory depends on summed similarity (S). Let $P(j)$ represent feature j of the probe and $T(i, j)$ be the corresponding features of memory trace i. Then the similarity of trace i to the probe j is computed as:

$$S(i) = \sum_{i=1}^{N} P(j)T^{(i,j)}/N$$

where N is the total number of features that are nonzero in either the probe or the trace. Activation of a trace or A is the cube of the similarity, so:

$$A(i) = S(i)^3$$

Raising the similarity to the third power increases the signal-to-noise ratio as it increases the number of poorly matching traces required to overshadow a trace that closely matches the probe. When a probe activates a trace in SM, information is returned in the echo. The echo is assumed to have two properties, intensity and content. If M is the total number of traces in memory, the intensity I is given by:

$$I = \sum_{i=1}^{M} A(i)$$

If there are no matching traces, than the expected value of I or $E(I) = 0$. Otherwise $E(I) \; ! = 0$. The variance of I depends on the number of matching traces. Frequency judgments and recognition judgments are assumed to be based on echo intensity. For the j-th constituent features the content of the echo $C(j)$ is:

$$C(j) = \sum_{i=1}^{M} A(i)T(i,j)$$

These C values can range from negative to positive and are assumed to be immediately available in PM. They form the basis for frequency judgments and recognition. A one-element version of MINERVA has also been able to give a good fit to some paired-associate learning data.

REM

REM (Retrieving Effectively from Memory) is an update of the SAM (Search of Associative Memory) model, which in turn was an update of the original Atkinson and Shiffrin buffer model. REM is designed primarily to deal with explicit episodic recognition memory. The model (or at least one version of it) is given in ten sets of linear equations specifying the likelihood ratios and their distributions. There is no room for a detailed discussion here; the interested reader is referred to the appendix of the original article (Shiffrin and Styvers, 1997). All we can do here is present the basic outline.

Like MINERVA, memory is assumed to consist of separate images, which are represented by a vector V of geometrically distributed features such that:

$$P[V = j] = (1 - g)^{j-1}g, j = 1, \ldots, \infty$$

For recognition, an error-prone copy of the item is stored, and for retrieval this probe is matched in parallel with all of the n words on the list. A Bayesian decision rule is used, and the odds are:

$$\Phi = \frac{1}{n}\lambda_j$$

The parameter lambda (λ) can be written in terms of the probabilities in three different ways (eqn [3], [4A], or [4B]), and these are used to generate the predictions of the model.

TODAM

TODAM is more a computer simulation model than a formal mathematical model. Unlike MINERVA and REM, TODAM is a distributed memory model where all information (item information and associative information) is stored in a common memory vector. The big difference between TODAM on the one hand and MINERVA and REM on the other hand is that the latter two are 'localist' models where information (items or associations) is stored in separate 'bins' (locations) as in a computer memory, while in TODAM everything is assumed to be stored in a common memory system and no search is required. As has been mentioned, it assumes direct access but, like MINERVA and REM, the retrieved information is 'noisy.' All three of these models focus on the same data base and each model can do a creditable job explaining some of the vast data in the literature but not all of it. Eventually the dust may settle (and I use the metaphor advisedly) and we may be able to say with some assurance that one model is better than the other two, or some other model is better than all of them, but that is a job for the future.

Applications to Data

There are many reliable empirical phenomena from studies of short-term memory and each of these three model has demonstrated the capacity to explain (a nonoverlapping) subset of them. One of the most important empirical effects is similarity. Similarity effects in human short-term memory have long been known. In a classic early study, Conrad (1959) found that acoustic similarity had a major effect on response accuracy in a simple memory-span task. It was a very elegant experiment; using a distinctive features analysis of his stimulus letters, Conrad showed a monotonic decline in the recall accuracy for single substitution errors (four letters out of five in a memory span task were correctly recalled but the first was not), and the greater the overlap in distinctive features the worse the performance. Neither TODAM nor SAM should have any trouble dealing with these similarity effects, but MINERVA, with ternary vectors, might have more trouble. However, if it were assumed that similarity was measured by the dot product or cosine, then MINERVA could probably deal with Conrad's similarity effects as well.

There are very many more reliable empirical effects in the study of short-term memory, but it is not possible to deal with any more of them here. A recent review of the field (Kahana and Caplan, 2002) presents a very comprehensive review and evaluation of these data and it will be interesting to see how these various models (and others yet to appear) can deal with them.

Other Areas

I have focused on these three particular models of human memory (TODAM, MINERVA, and REM) because they are relatively well developed. They permit some experimental resolution because they all can deal with the same broad range of data. There is yet a fourth area of short-term memory that should be mentioned if only briefly, and that is free recall. The free recall paradigm is very simple: present a short list of items (often common words) and ask the subjects to recall them in any order they wish. As has been noted, the classic result is a relatively extensive (seven or eight item) recency effect, a short (three or four item) primacy effect, and a middle asymptote (level part) that depends on the presentation rate and list length. The two major models here are the Temporal Context Model (TCM) (Howard and Kahana, 2002) and Donald Laming's work (Laming, 2010).

A different approach to associative learning has been provided in a series of studies and models in the Broadbent tradition by Burgess and Hitch (1999); these models assume item-to-position associations rather than item-to-item associations. There is the Dennis and Humphreys model (Dennis and Humphreys, 2001) and the Brain-State-in-a-BOX or SOB model in Australia by Farrell and Lewandowsky (2002).

Most prominent in the area of recognition memory is the random walk (diffusion model) of Ratcliff (1978). The Ratcliff model followed closely after Link's random model now incorporated in Link's WaveTheory model (Link, xxxx) with ideas that go back as far as Einstein. These are very different models of memory using a random-walk algorithm for the accumulation of information over time and have given very detailed (and accurate) predictions of accuracy and latency as a function of drift rate. Unfortunately there is simply no space here for an adequate coverage of any of these models, but the interested reader can track them down and see how they fit into the growing list of models of short-term memory and learning.

Finally, some time ago a very elegant (and widely ignored) model was suggested by Kanerva (1988), in which "many memory storage registers participate in a single write or read operation. Storage locations and their addresses are given from the start and only the contents are modifiable" (p. 61). Retrieval works on a best match principle. As the author says, "The mathematical feasibility of distributed storage is the main result of this study."

Conclusion

As has been noted, there are a host of reliable short-term memory effects and a fair number of quantitative models that have their various successes and failures. I think it is fair to say that at this point this is no convincing evidence that any one model is clearly superior to the others. However, as time passes, the evidence will come in and some resolution should result. While one may deplore the lack of resolution of these issues, perhaps we should be pleased by the developments that have occurred. Our models and theoretical concepts are still relatively primitive compared to those of the 'hard' sciences, but still we have come a long way since Ebbinghaus. Our learning and memory models are more comprehensive and sophisticated than ever before. Our goal should be to develop

mathematical and simulation models of human memory and learning that can do justice to the vast accumulation of experimental data that has been collected over the last 100 or more years of experimentation since Ebbinghaus.

Men's Health

Richard G Owens, School of Psychology, University of Auckland, Auckland, New Zealand

Abstract

It is increasingly being recognized that just as the demands of female gender-role expectations impact negatively on the health of women, so too do the demands of male gender-role expectations on men. It is widely recognized that life expectancy for men is, in most developed countries, lower than that of women, and such discrepancies can be linked, at least in part, to behaviors associated with 'being a man.' Morbidity, too, is affected by conformity to the expectations of hegemonic masculinity, with men differing markedly from women across a range of dimensions including emotional expression, body-image expectations, sexual behavior, and help-seeking. Ironically, stepping outside traditional male norms may also have adverse effects on health as such men become to a greater or lesser extent excluded from mainstream society. The suggestion, therefore, is that rather than seeking solutions at an individual level, there is a need for a wider societal revision of the specific expectations place upon both men and women.

Introduction

A number of factors have, over recent decades, led to increasing recognition of the extent to which socially determined gender roles impact on health. Much of the early work in this field, developed within a context of hegemonic masculinity, was concerned with ways in which social constructions of gender affected adversely the health of women (see e.g., Lee, 1998). It is perhaps natural that when attention is paid to issues such as gender, the main focus should be on those groups most obviously disadvantaged by these expectations, but recent years have seen increasing recognition not only of the ways in which men, as well as women, are disadvantaged by gender roles, but also of the fact that the interplay of male and female gendered expectations does not result in a zero-sum game. That is to say, it is increasingly apparent that deconstructing and challenging the expectations on one sex does not necessarily imply a disadvantageous outcome for the other. Indeed, close examination of the processes involved leads to the conclusion that the challenging of conventional expectations may prove beneficial to both men and women. This applies not only in terms of such dimensions as economics, but also, significantly, to the health of the individuals concerned.

From early and often piecemeal beginnings (e.g., Helgeson and Lepore, 1997), a picture has begun to emerge, which demonstrates the wide-ranging impact on men's health of their conformity (or otherwise) to perceived gender-role expectations. Such effects can be seen across a wide range of settings, including increased exposure to and risk of threats to health, decreased access to or take-up of protective and other health measures and increased mortality. Some of these have previously been described in various contexts including a special issue of the *Journal of Health Psychology* (May 2002) on men's health, and the publication of *The Psychology of Men's Health* (Lee and Owens, 2002). The present article thus has two main aims: (1) to present in concise form some of the arguments presented in earlier work and (2) to update and develop some of the material previously available.

Men and Mortality

In a world in which to be a male is often seen to be placed in a privileged position, it perhaps appears anomalous to note that in most developed countries, the life expectancy of men is substantially lower than that of women. By exactly how much women can expect to outlive men varies. In the United States, for example, men can expect to die around 6 years younger than women, in France nearly 8 years younger, and in the UK almost 5 years younger. The reasons underlying this are many and varied, and at various times, a range of mechanisms have been put forward. Not surprisingly the discrepancy has traditionally (see e.g., Madigan, 1957) been linked to biological or physiological factors. For example, Waldron (1995) attributes the bulk of the effect to factors such as the possible protective effect of estrogen on coronary heart disease (implying that women's risk of heart disease will, at least premenopausally, be lower than that of men). Certainly, there is evidence, which is consistent with such a suggestion; for example, in the United States 75% of those dying from heart disease below age of 65 years are men, and in the Framingham Study (Lerner and Kannel, 1986) women showed only around half the cardiac mortality of men. Clearly, however, this can be only part of the story. First, it should be noted that the male–female differences in biology have been around as long as the human race, but significant sex differences in mortality only started to appear toward the beginning of the twentieth century (Gonça et al., 1999). These biological differences of course are the same in all countries, yet as we have seen above there is considerable international variation in the size of the discrepancy, e.g., between France and the UK.

Second, close examination of the pattern of mortality differences reveals that for many developed countries, the number of surviving women exceeds that of surviving men from about age of 25 years, well before there is any significant impact of coronary heart disease on mortality. Indeed, plotting of the differences in mortality against age reveals that the discrepancy tends to peak at two points. One late in life, as may be expected under an assumption of the effects of

coronary heart disease, but another substantial (and, when corrected for raw mortality rates, greater) discrepancy between ages 20–35 years. It appears that in addition to any physiological process affecting such problems as heart disease, many more men than women are dying 'prematurely.' The discrepancy at these younger ages is more commonly ascribed to factors such as men being typically being involved in more dangerous occupations and activities, being greater risk takers, and so forth. It is a small step from such an observation to the acknowledgment that much of this can be linked to these activities being seen as, predominantly, 'typically male.' Thus in Australia, the three-quarters of homicides who are 'nonintimate' (i.e., do not involve the death of someone close such as a current or ex-partner) men are about three times as likely to be the victims as women (Pratt and Deosaransingh, 1997). Other causes of death show similar patterns, for example, men are three times as likely as women to be killed in motor-vehicle accidents (Li et al., 1998), largely reflecting men's greater exposure to risk (e.g., time spent traveling). Similarly, sporting injuries and fatal accidents are more common among men than women (see e.g., Williams et al., 1998). Notably, however, the idea that men are greater risk takers turns out to be somewhat more complex, and only true to the extent that men are more likely than women to be involved in higher risk activities. If one corrects for the greater extent of men's involvement than women's, then these discrepancies disappear or even, in some cases, reverse. Thus, it is not simply an issue that can be dismissed in terms of individual analyses and 'men doing stupid things,' but rather requires a broader societal analysis, which highlights the gender expectations, which socialize men toward these activities while simultaneously directing women away. Observations such as these have led some workers to investigate the role of factors such as patriarchal attitudes on mortality differences. In one such study (Stanistreet et al., 2005), 49% of the international variance in male–female mortality differences could be predicted from a country's rate of female homicides, which the authors used as a proxy measure for the degree of patriarchy. Thus, it was argued, the more patriarchal a society, the earlier men could expect to die relative to women.

Once the potential effect of gender-role expectations is recognized, of course, it also becomes apparent that there is likely to be an interaction between these and the biological factors to which the discrepancies have traditionally been attributed. In a society, for example, which regards smoking as an acceptable behavior for men but not for women we may expect decades later to find that deaths from heart disease and lung cancer, even with all other things being equal, will be higher among men. In passing, it is worth remembering that a common concern for those working in the population health field, of course, is the convergence of smoking rates for men and women; Harris (1983) notes that in the United States by 1920 over half the male population smoked, whereas it was not until 1950 that a third of the female population did so. Almost like an experimental multiple-baseline design (Sidman, 1960), the data show that changes in important outcome variables – in this case mortality differences – can be linked to earlier changes in societal factors – e.g., the acceptability of smoking across the sexes.

How Conforming to Gender Expectations May Adversely Affect Men's Health

Although it has been said that mortality is hard to beat when looking for a dependent variable, the reality is that there is more to health than simply being alive. We have seen already how mortality can be related to differences in societal expectations for men and women. It would be odd, if these effects on mortality were not also reflected in morbidity, and indeed much of the evidence supports the supposition that 'being a man' may be, in many respects, bad for one's health. Around the world, implicit or explicit exhortations imply that to be 'a man' is to be more than just an adult male. A Japanese story tells of a Samurai saying to his son "I would not have you a priest, of whom there are many, but a man, of whom there are few." In the UK, Rudyard Kipling's poem 'If,' voted as the nation's favorite, calls upon the man to "force your heart and nerve and sinew …" and to "… fill the unforgiving minute, with sixty seconds' worth of distance run …". A Chinese idiom "不到长城非好汉" roughly translates as "if you haven't climbed the Great Wall, you're not a real man." The 1980s saw the whole edifice of expectations of masculinity satirized in Bruce Feirstein's *Real Men Don't Eat Quiche*, a book which would have undoubtedly had very little success had the expectations parodied therein not been familiar to the reader.

Unfortunately, the kinds of characteristics that distinguish the 'real man' from his failing counterpart are often ones, which have a direct or indirect bearing on his health. Thus men are expected to display emotions differently to women; for men, external positive emotions such as love are less likely to be expressed, as are internal negative ones such as pain or symptoms of illness. By contrast, men are actively encouraged to express external negative emotions such as hostility. Numerous writers (e.g., Courtenay, 2003) have commented on how such restrictions on emotional expression might be expected to impact on health. This may occur directly – for example, two men, each expressing hostility may be a recipe for physical violence and subsequent injury. There may also be indirect effects; Pennebaker (1997) and his colleagues, for example, have demonstrated across a wide range of studies that the experience of disclosing negative experiences can have positive effects on elements of immune functioning, with the clear implication in the present context that men who are reluctant to do so will fare worse than those who do.

Other expectations placed upon the 'real man' can also be seen to impact on health. Research in women's health has highlighted the negative effects of the 'keep young and beautiful' expectation in terms of problems such as anorexia nervosa, but men too have expectations regarding appearance; in particular men, are expected to be physically strong and fit. While, this might at first glance be expected to be, from the point of health, a positive element in traditional male expectations, the same could be said of the requirement that women avoid carrying excess body fat. In both cases, unfortunately problems arise when the expectation is taken to extremes, or when extreme measures are taken to meet the expectation.

As far as men's physical strength and fitness is concerned, the most obvious example of taking the expectation to extremes is in the world of competitive bodybuilding (note that competitiveness itself is seen as a traditionally male

characteristic). One of the most notable pioneers of bodybuilding, of course, Charles Atlas, famously based his whole advertising campaign on the notion that it was bad to be a 'seven-stone weakling' who has 'sand kicked in his face,' and the crude strip cartoons that accompanied his campaign made it clear that the story of the weakling who became strong and physically overwhelmed the 'beach bully' was that of the quintessential hero.

Unfortunately, while the 'dynamic tension' taught by Charles Atlas was perfectly capable of producing a strong healthy body, subsequent years have taken the objective of bodybuilding so far beyond the Atlas physique that achieving a body which would win today's competitions requires distinctly unhealthy strategies. Prominent among these is the use of substances such as anabolic steroids, a risky behavior, which is by no means restricted to bodybuilding (note the disqualification of the 1988 Olympic 100m champion, Canadian Ben Johnson when it was found that he had taken banned steroids).

As with problems relating to emotional expression, the health risks of illicit steroid use may be both direct and indirect. Even under ideal conditions, extensive use of steroid medications may give rise to concern about health problems such as disturbed lipid metabolism, prostate enlargement and liver damage. In practice, given that the steroids are obtained and administered under conditions of secrecy, the direct effects are likely to be exacerbated by indirect health consequences including added risks from taking drugs whose exact provenance may be unknown (and therefore, may have problems such as being outdated, or being veterinary rather than human preparations) and associated behaviors such as needle sharing.

Should one be tempted to dismiss such problems as only applying to a tiny minority (only a percentage of bodybuilders who are themselves only a small percentage of the male population) it should be noted that the figures are nevertheless significant. Wroblewska (1997) in a review of published surveys found rates of anabolic steroid use ranging from around three-quarters of competitive bodybuilders to 4% of males in general. A Swedish study of 16–19 year students found that while only 0.4% of females had used steroids the figure rose to 2.7% for males. Clearly, the use of steroids is not only restricted to those in a few sports with low participation rates.

Concern with appearance, of course, is intimately linked to perceptions of one's own attractiveness, particularly one's attractiveness to potential sexual partners. Once again, however, we find that the social expectations on men are notably different to those on women. A common classroom exercise illustrates this well; students are asked to write down as many names they can think of to describe a woman who has casual sex with anyone to whom she's attracted, even if she hardly knows them. It takes only a short time to come up with a list of derogatory expressions such as 'slut,' 'slag,' 'tart,' and so on. On trying to do the same for a man who exhibits the same behavior, the most obvious name is 'James Bond.'

Once again, it might appear at first glance that such a double standard will be unequivocally advantageous for men, yet a closer examination reveals that it is far from unproblematic. The expectation that men will engage in indiscriminate sexual behavior, may bring a number of health concerns, most obviously by increasing the risk of exposure to sexually transmitted infections. While one might argue that in today's sexually aware modern world, the risk of such infections can be minimized or eliminated by practices such as condom use, the reality is that males are more reluctant than females to suggest condom use (Troth and Peterson, 2000) and more likely to meet criteria for high-risk activity (e.g., multiple partners, inconsistent use of condoms) than women (Newman and Zimmerman, 2000).

It is not only in terms of exposure to risk, however, that traditional male roles have a potentially negative effect on health. With the most gender-neutral society imaginable both males and females would still become sick. Unfortunately, the current gender-role expectations associated with being male not only conspire to heighten men's risk of illness, but also affect their involvement with the systems designed to deal with such illness.

A stereotype that demands men should be 'naturally' strong, resistant to disease, able to cope with pain, and unconcerned with minor problems suggests that they may benefit less from structures in society, which are designed to promote health and minimize the seriousness of disease. As expected the data indeed show, across a range of populations and ages, that men engage in more activities that are harmful to health (e.g., smoking, pursuing unhealthy diets, heavy drinking) than women (e.g., Uitenbroek et al., 1996; Holtzman et al., 2000). A considerable amount of evidence suggests that men use health care and screening services less than women (Schappert, 1999) even when the potentially biasing effects of gynecological services are taken into account (Stoverinck et al., 1996), although the evidence is by no means unequivocal, with a Scottish survey (Macintyre et al., 1999) finding no evidence for male–female differences in symptom reporting or health care. The picture appears complex, with the same research group finding that men were less likely to report a range of symptoms than women, but that when they did so they were just as likely to have consulted a doctor (Wyke et al., 1998). One area, however, where men's behavior appears to be consistently different to women's is the use of psychological services, with men much less likely than women to seek out psychological services for themselves (see e.g., Jorm, 1994). Such reluctance to make use of psychological services is, of course, consistent with a prescriptive male stereotype, which expects men to be strong, self-reliant, and emotionally restrained.

In terms of self-reliance, it is interesting to note that men and women may differ in terms of the health-related actions they take or the areas they neglect. Studies have reported that men are less likely than women to be interested in making healthy lifestyle changes (Gabhainn et al., 1999), and that when they do make health-related lifestyle changes these differ from those typically made by women. Thus, Welsh et al. (1998) in studying health-related attitudes of male and female students found that the former tended to focus on physical activity while the latter focused on diet. Similarly, men appear to know less about health and healthy lifestyles than women, with studies showing that popular media tend to direct such information toward wives and mothers (Lyons and Willott, 1999). While this may be seen as pragmatic, the result may be that the messages are less effective; when women attempt to control the health-related aspects of husbands' behavior this is likely to have less effect than self-directed change, and of course

such campaigns may have little impact on those men who are not in a close relationship with a woman. Indeed, the evidence over many years has consistently indicated that the health of men who are unmarried is worse than that of those who are. Similarly the loss of a partner, whether it be through divorce or bereavement, is associated with more negative changes in health behaviors for men than for women (Umberson, 1992; Clayton, 1990; Byrne et al., 1999). One implication of such findings is that if health campaigns and similar interventions are to succeed, they may need to have a degree of gender-specificity if they are to be maximally effective.

A picture thus emerges whereby aspects of traditional expectations within masculinity may be seen as having potentially serious negative effects on the health of men who subscribe to them, and moreover that the greater the extent to which men attempt to conform to the 'strong, unemotional, self-reliant' image, the greater the negative impact. Of course, few men subscribe unquestioningly to all aspects of this image, and some men will fail to meet, or will positively reject the expectations placed upon them. Ideally, one might hope that in doing so, the negative effects of the traditional male role would be attenuated or eliminated. In practice, however, as with men who subscribe to traditional expectations, the results of rejecting such a role may similarly be complex and problematic.

How Rejecting or Failing to Meet Gender Expectations May Adversely Affect Men's Health

In many societies, it remains the case that the overwhelming majority of men conform to some degree, at least, to traditional male expectations. Thus, in Australia around 90% of married men with children are in the paid workforce, while only 40% of women with children under 15 do so, supporting a traditional notion that men's primary role is to be a breadwinner, providing for the family, while women's is to provide nurturing and care for children. One outcome of this is a potential conflict between social expectation and the reality of family life. Thus, in countries where there is a contraction in the job market with consequent high unemployment, there is evidence that this impacts particularly on men. For example, Pritchard (1992) in a study of suicide rates in Europe during the 1970s and 1980s found that these were significantly correlated with the associated rates of unemployment.

For the men who do have jobs there may, particularly for fathers, be a perceived role conflict if they also take on domestic responsibilities – to a higher degree than do women in similar situations (Greenglass et al., 1988; Duxbury and Higgins, 1994). Such role conflict may not simply result from their own internalizations of traditional expectations, but also from others. Thus, an Australian study (Lobo and Watkins, 1995) found unemployed men who attempted to take on traditional 'women's work' within the house being met with resentment from wives who perceived their husbands as failing to keep 'their side of the bargain,' with associated impact on the quality of the marital relationship and relationships between fathers and children.

For some men, of course, their stepping outside a traditional role expectancy may be seen as global and irretrievable, particularly, in the case of men whose sexual preferences do not conform to the perceived norm of exclusive heterosexuality. Homosexual, bisexual, and transgender males are routinely perceived as deviant and threatening, to be excluded from 'normal' society. Such drastic exclusion continues despite decades of research challenging the essentialist nature of sexual preferences, the evidence that these may change over time, and the recognition even from the middle of the last century that a range of positions may exist between the stereotypes of 'exclusively homosexual' and 'exclusively heterosexual.' Ironically, the man who is attracted to other men may end up with a strong commitment to other aspects of traditional masculinity, as evidenced by such activities as spending hours building a hypermasculine body (possibly with the help of steroids, as mentioned earlier) and becoming involved in extensive sexual promiscuity (with the associated increased risk of contracting sexually transmitted infections). Despite subscribing heavily to such other masculine norms, however, the centrality of sexuality in Western society means that he remains an outcast, unacceptable in 'normal' society, with the associated stresses of either coping with rejection or maintaining secrecy about his sexual identity.

The picture that begins to emerge, therefore, is that, however, a man chooses to play the hand he is dealt, the expectations of traditional masculinity, whether he subscribes to them or not, are likely to impact negatively on his health in a range of ways. It is important, therefore, to recognize that the way forward involves not simply individual men choosing whether or not to subscribe to societal expectations, but a change in those expectations themselves. Such change may be slow, and will almost certainly need to arise from changes in a variety of areas – again, operating not simply at the individual but also at the broader societal level.

Societal Messages around Gender-Role Expectations

As things stand, the socialization of men and women into specific gender roles operates through a variety of routes. It has long been recognized that even before starting school, most children have little difficulty differentiating mothers' and fathers' household and occupational tasks (Hartley, 1961), with messages around the differing expectations apparent even in children's nursery rhymes. One such, for example, "Sugar and spice, and all things nice, that's what little girls are made of; slugs and snails and puppy dog's tails, that's what little boys are made of" illustrates clearly that girls are expected to be pleasant, clean and 'nice,' while for boys it is acceptable to be grubby and unpleasant – messages which soon translate into differences between what is acceptable play for boys and girls, and the extent to which boys and girls are differently encourages or discouraged from different forms of play, physical punishment, and so on.

Throughout life the receipt of such messages continues; in popular media such as television, it has been reported that male characters are considerably more likely to be obese, to smoke, to drink, and to participate in high-risk behaviors. Conversely, females are portrayed as having the highest health risks and being more likely to die, while men and boys who are risk-takers or victims of violence are portrayed as either

invulnerable to harm or likely to recover from such harm with marked rapidity (Courtenay, 2003). Magazines and television programs aimed at men are also, in the United States, more likely to advertise substances such as alcohol and tobacco (Klein et al., 1993). Observations such as these indicate the need for a substantial change in the societal messages and portrayals of male-appropriate and female-appropriate behavior, if the negative health impacts of gender roles are to be addressed.

Beyond Gender

Having said all of, which it is, of course, important to remember that while men's health is significantly affected by gender-role expectations, this is not the whole story, and the role of biology and anatomy cannot be neglected. Thus although the suggestion, noted earlier, that sex hormone levels might account for the bulk of male–female differences in life expectancy is probably an overstatement, there is no doubt that such factors will have an effect. Anatomy, similarly, will lead to differences in the health problems of men and women, irrespective of whether or not the two sexes have differing societal expectations placed upon them. Cancers such as testicular cancer, primarily affecting men while still young, and prostate cancer, more associated with advancing years, will continue to take their toll in the male population. Even so, however, it is perhaps also useful to note that gender roles and biology are intertwined. In many countries, for example, it is routine for women who attend for medical consultations to be offered, routinely, health checks such as cervical smears; it is much less common for men to be offered such things as Prostate-specific antigen checks to identify early signs of prostate cancer.

It is also important to note that the very biological processes involved in many diseases and health problems may themselves interact with the social expectations. Remaining with prostate cancer for the moment, there is some suggestion that the more cigarettes a man smokes, the higher his risk of prostate cancer; the heaviest of smokers have a 24–30% higher risk of death from prostate cancer than nonsmokers (Huncharek et al., 2010). Thus, as long as society perpetuates messages of masculinity that inflate men's risk of becoming smokers (e.g., risk-taking, invulnerability, etc.) there will continue to be an impact even on those diseases whose causes are dominated by biological factors.

Conclusions

Inevitably, the present article can do little more than provide a broad overview of issues relating to men's health and in particular the relationship between this and societal gender-role expectations. Nevertheless, it is clear that while any understanding of men's health inevitably requires an appreciation of anatomical, physiological, and other biological differences between men and women, such understanding is both insufficient to give a complete picture and to indicate appropriate routes for health improvement. The problem is exacerbated, and likely to continue so, by changes in the patterns of disease in modern society. Where, a century or so ago, things like acute infectious diseases (e.g., smallpox, influenza) accounted for a high proportion of deaths across both sexes, the development of technologies such as antibiotic therapy and immunization has led to the role of such diseases being dramatically reduced (or, in the case of smallpox, eliminated). The diseases of the modern world – cancers, heart disease, hypertension, and so on have much closer links to lifetime patterns of behavior. Moreover, the mortality associated with such diseases may similarly be closely linked to behavior, not just in terms of things like seeking out health care and the availability of screening for early detection, but also in terms of behaviors that influence the seriousness of a disease once it has developed – as we have seen in the example of prostate cancer and smoking. From birth, we are exposed to messages from a variety of sources, which prescribe certain activities and proscribe others, often on the basis of whether we are male or female. There is now ample evidence to link such societal conventions to a variety of health behaviors, only a handful of which it has been possible to outline in the present article. As far as men are concerned, the continued expectation that they will adopt certain lifestyles, behave in particular ways is likely to expose them to increased mortality and morbidity with respect to a variety of health problems. To the extent that they opt out of, or fail to meet such expectations, they are likely to experience feelings of stress and failure, again impacting on both physical and mental health. Looked at from such a perspective, any realistic attempt at improving the health status of men in today's society will need to take into account the demands placed on men by that society.

Mental Causation

Jens Harbecke, Witten/Herdecke University, Witten, Germany

© 2015 Elsevier Ltd. All rights reserved.

Abstract

This article focuses on the philosophical problem of mental causation as it has been debated in mainstream metaphysics of the last 50 years. After a brief overview of the history of the problem, the assumptions constituting it are made explicit and shown to be inconsistent. In a second step, various arguments supporting canonical solutions to the problem are summarized, including interactionist, epiphenomenalist, identity theorist, and overdeterminationist approaches. The final section highlights the most recent developments of the debate by presenting a family of compatibilist approaches as well as interventionist theories of mental causation.

Introduction

In interpreting the behavior of others, we intuitively credit thoughts, beliefs, desires, emotions, memories, representations, and sensations causal powers on various kinds of observable occurrences, such as body movements, speech acts, and cooperative actions. For instance, we causally explain Suzy's walk to Dairy Queen by her desire to eat ice cream combined with her belief that she can buy it there. Moreover, we take it that Tamar's slowing down of the car was partly caused by her perception of a red stop sign on the road in front of her and her knowledge of its meaning.

Such mental causation speak is not limited to folk psychology. In clinical, cognitive, and developmental psychology, mental causal language is prevalent in the sense that the mind is described as an information-processing system that transforms stimuli inputs into representations. These representations, typically in conjunction with further informational data, are then processed into behavioral outputs.

A fundamental question in the context of such causal ascriptions is whether mental phenomena can in fact be causes of physical phenomena in the physical world, given that the mind is not physical itself in any obvious way. It is now widely believed that this question points to a philosophical problem: the 'problem of mental causation.' It is a philosophical problem in the sense that it is based on a set of assumptions, all of which enjoy credence in isolation, but which cannot all be true.

This article focuses on the philosophical problem of mental causation as it has been debated in mainstream metaphysics of the last 50 years. After a brief overview of the history of the problem, the assumptions constituting it are made explicit and shown to be inconsistent. In a second step, various arguments supporting canonical solutions to the problem are summarized, including interactionist, epiphenomenalist, identity theorist, and overdeterminationist approaches. The final section highlights the most recent developments of the debate by presenting a family of compatibilist approaches as well as interventionist theories of mental causation.

A Brief History

The problem of mental causation is a comparatively young philosophical problem in the sense that ancient and medieval philosophy did not consider questions of mental causality as genuinely problematic. To be sure, the relation of mind and body was already debated in Greek philosophy. Plato (427–347 BCE) in the *Republic* and the *Timaeus* offered an analysis of the human soul (*psyché*) as consisting of three parts all of which inhabit the human body. Two of these, the appetite and the spirit, are intimately connected to the body and die with it. Only the rational ingredient, or the *logos*, is immortal and persists even when the body is destroyed. The logos was conceived of as having causal effects on bodily movements and human actions by playing a part in deliberation and decision making. However, Plato does not seem to have viewed such soul-to-body causation as particularly problematic.

Aristotle (384–322 BCE) in his *De Anima* presented a view according to which nothing in the soul is wholly independent of the body as Plato thought. But neither is the soul a conglomerate of material atoms as Democritus believed. Rather, each soul essentially inheres in a body without being identical to it. When humans act or behave in some way, this is always the result of body and soul working together (cf. Caston, 2009, p. 318). From a modern perspective, the fact that Aristotle did not explain in detail how this 'working together' proceeds precisely is unsatisfactory. For instance, the theory leaves open whether human actions have sufficient bodily causes, or whether they only have sufficient causes that are partly constituted by the activities of body and soul.

The uncritical attitude toward the causal powers of the mental that characterized ancient and much of medieval philosophy of mind changed only when 'physicochemical' thinking gradually spread in early modern philosophy, notably through the works of René Descartes (1596–1650). By invoking a skeptical argument based on the observation of the uncertainty of the outside world, Descartes concluded that the mind and body must be quite distinct kinds of entities, namely two kinds of substance. Substances are traditionally described as entities that can exist all by themselves. In this sense, smiles and colors are not substances, but faces (that can smile) and iron rods (that can be brown) probably are.

Descartes' dualist ontology postulated a thinking substance (*res cogitans*) and an extended substance (*res extensa*). The philosopher did not seem to have been particularly bothered by questions about causal interactions between the substances until in 1643 Elizabeth of Bohemia in a now famous letter demanded an explanation from him of "(…) how man's soul,

 http://dx.doi.org/10.1016/B978-0-08-097086-8.63095-7

being only thinking substance, can determine animal spirits so as to cause voluntary actions?" (Adam and Tannery, 1904, III, p. 661). Pierre Gassendi in his *Objections V* remarked in a similar way, "How can there be effort directed against anything, or motions set up in it, unless there is mutual contact between what moves and what is moved? And how can there be contact without a body (…)?" (Cottingham et al., 1985, p. 237). Descartes responded in his *Passions of the Soul* of 1649 (Adam and Tannery, 1904, XI) by arguing that a suitable mediating instance can satisfactorily explain the interaction between different kinds of substances. The philosopher had identified the human pineal gland as the locus of this mediation.

Descartes' reply has convinced few philosophers ever since, but it may have been less ad hoc than it appears at first. Gottfried Wilhelm Leibniz (1646–1716) provided a famous reconstruction of Descartes' theory, according to which the latter was perhaps the first philosopher of mind to recognize a particular kind of conservation principle that strongly constrains the mediating model. This conservation principle contends that the quantity of energy and matter remains constant in any closed physical system. Consequently, causation between *res cogitans* and *res extensa* cannot be a matter of exchanging energy quanta. However, the principle allows for spontaneous alterations of the *vectorial direction* of energy quanta within closed physical systems, and it is here where Descartes saw the mind in action. However, according to Leibniz, Descartes was able to maintain this hypothesis only because "(…) in his times the natural law stating also the direction of matter is preserved was not yet accepted" (*Monadology*, §80, Leibniz, 1890, VI, pp. 620–621). Even if Leibniz was right about Descartes holding this view (cf. McLaughlin, 1993), the question remains how in the pineal gland a nonextended and nonlocalizable mental substance can get in contact with physical substances.

In the centuries following Descartes, virtually all prominent philosophers aimed to provide some answer or other to the problem of mental causation (cf. for instance Leibniz, 1890, 6; Spinoza, 1677, Section 2.1.2; Kant, 1910, 1:19–21; Schopenhauer, 1980, 3, pp.171–173; Huxley, 1893). However, it was only in the second half of the twentieth century that the question of how the mind can be causally active made its way into mainstream metaphysics (cf. Kim, 1997). The problem surfaced already in C.D. Broad's classic *The Mind and Its Place in Nature* of 1925, in Ludwig Wittgenstein's reflections on mentality and mental discourse, as well as in Gilbert Ryle's *The Concept of Mind* (1949). However, its modern metaphysical version was presented by Place (1956), Feigl (1958), and Smart (1959) only in the late 1950s. This version is less concerned with the logic of psychological explanations and focuses on metaphysical causal connections.

Finally, the standard formulation of the problem that still forms the basis of today's debate was proposed in the late 1960s by authors such as Malcolm (1968) and Goldman (1969), who construed the puzzle as a set of incompatible assumptions. The subsequent debate in the 1970s centered on functionalist theories of the mind (cf. Putnam, 1967, 1975; Fodor, 1974). Since functionalism defines mental phenomena as inherently causal and since it subscribes to a token-identity theory, this approach seemed to leave little room for the problem of mental causation. In the late 1970s, however, the feeling spread that also functionalism does not provide a satisfactory solution. Among those philosophers who expressed this worry against functionalism, Kim (1979, 1985) developed the most prominent attacks. From the 1980s onward, the literature on the problem of mental causation has mushroomed, offering a large collection of competing answers to the question of how the mind can have effects in a physical world. A small collection of authors representing the spectrum of positions developed in this late stage of the debate on mental causation is Baumgartner (2009, 2010), Bennett (2003), Bishop (2006), Block (1997, 2003), Bontly (2002), Campbell (1970), Crisp and Warfield (2001), Dardis (2008), Elder (2001), Fodor (1997), Harbecke (2008, 2010), Harbecke and Atmanspacher (2012), Kim (1998, 2003, 2005), Loewer (2007), MacDonald and MacDonald (1986), Marras (2007), Menzies (2008), Menzies and List (2010), Noordhof (1999), Papineau (2002), Raatikainen (2010), Schiffer (1987), Sosa (1984), Weslake (2009), Woodward (2008, 2011), and Yablo (1992a,b). As a result, the problem of mental causation is one of the most widely discussed problems in contemporary philosophy.

The Premises of the Problem

The standard formulation of the problem of mental causation construes it as being constituted by the following four plausible assumptions that, if conjoined, provably imply a contradiction (cf. Harbecke, 2010, pp. 73–74 for a rigorous formalization and a proof for the inconsistency).

(P1)	Some mental events cause physical events.
(P2)	Every physical event has a physical cause.
(P3)	Mental events are not identical to physical events.
(P4)	Physical events are not causally overdetermined.

The following deliberations make clear why the four assumptions all seem plausible in isolation, but are inconsistent with one another nevertheless. Assumption (P1) departs from observations as those mentioned above: Both in everyday and folk-psychological situations as well as in certain scientific contexts, we accept ascriptions of causal powers to mental states or events as highly plausible. Allowing minds to be causes is in fact at the very core of our self-understanding as humans. As a consequence, many of us are convinced that some mental events cause some physical events (premise (P1)).

However, in contrast to the ancient philosophers and early modern thinkers such as Descartes, we now have available overwhelming evidence for the truth of physical principles stating a conservation of mass, energy, and vectorial direction of movement in closed physical systems. Moreover, recent neurophysiological research suggests that bodily movements can often be reliably predicted from prior neural activities. In other words, in the physical world as we know it today, no gaps open up that nonphysical causes could fill. Insights of this kind suggest that any physical event has a sufficient physical cause (premise (P2)). Hence, unless mental phenomena are nothing but physical phenomena, they can only be redundant causes.

But mental phenomena seem to be very different from physical phenomena indeed. Even though most of us would presume our mental life to occur more or less in the same place as our brain activities, opening a skull is quite useless for isolating mental phenomena. All that can be discovered there is gray and white matter, or perhaps neural activities if appropriate imaging techniques are applied.

Moreover, mental states are intentional in the sense that they have content or are 'about' something else and have a nonlocal nature in this sense. Physical phenomena do not have this property of 'aboutness' or nonlocality. But even many purely local mental phenomena are not obviously identical to physical phenomena as the mental kinds that they are an instance of do not seem to be coextensional with any physical kind. For instance, at some future point in time it will probably be possible for a sophisticated robot to entertain the genuine thought that grass is green. However, even then the robot's physical state will differ radically from that of humans when they entertain the thought that grass is green.

Coextensionality is at least a necessary condition for an identity of kinds, and an identity of kinds is usually considered a necessary condition for an identity of the local phenomena. For instance, within a fine-grained model of events (cf. Kim, 1973), the instantiated kinds are part of the identity conditions of events. All of this suggests that mental events are not identical to physical events (premise (P3)).

With respect to causal redundancy, many of us can conceive of cases in which two independent causes are responsible for the same effect. For instance, when Otto was about to enter the road, both Bertha and Anna yelled 'STOP!', which caused him to halt exactly on the edge of the sidewalk (if Otto had not stopped, he would have been hit by a car passing by). Both Bertha's and Anna's yelling 'STOP!' was sufficient for Otto's halting, and neither of the two yells is easily declared as the 'true' cause. But whilst an occasional overdetermination of certain effects seems quite plausible, it is difficult to believe that certain physical effects are systematically overdetermined by physical and mental causes. In other words, physical effects are not systematically causally overdetermined (premise (P4)), and mental events cannot be redundant causes – contradicting what we inferred above. The contradiction shows that premises (P1)–(P4) actually constitute a philosophical problem.

Does the Problem Generalize?

It is now widely believed that the problem of mental causation generalizes in at least four senses (cf. Harbecke, 2008, Section 1.6). The first one concerns the observation that a wholly analogous causal problem can be constructed, for instance, for phenomena referred to by the biological and chemical sciences. Mental phenomena may be unique in the sense that they have content, are not 'visible,' and are possibly external so that the problem of mental causation receives independent intuitive force. However, just like mental phenomena, biological and chemical phenomena are nonfundamental, or 'higher level.' In light of the completeness of physics, it is not immediately clear how such higher level phenomena can be causally efficacious for physical events in general.

The second sense concerns a distinction of 'macro properties' and 'micro-based properties.' Whereas micro-based properties were sometimes believed to be somehow inferable from micro particles, such as the properties of a mineral stone are inferable from the properties of its crystal lattice, macro properties including functional properties were usually considered as less transparently related to micro properties. As a consequence, the problem of mental causation was sometimes believed to concern macro properties only. However, in recent years, it has been shown that, if micro-based properties exist at all and are not identical to micro properties, an analogous problem of micro-based properties emerges (cf. Bontly, 2002).

A third sense in which the problem generalizes points toward the fact that the problem (P1)–(P4) can be reformulated in various ways. For instance, no matter if the causal *relata* mentioned by the premises are events (as done in Section The Premises of the Problem), properties, facts, or states, a version of the problem of mental causation emerges.

The fourth sense concerns the theory of causation presupposed. It is usually assumed that the problem occurs under Humean theories of causation, as well as under process and power theories of causation. It is currently more controversial whether the problem can be identified also within an interventionist framework (cf. Section Interventionsim and Mental Causation).

Canonical Solutions to the Problem

The contradiction implied by (P1)–(P4) allows us to reject any one of the four assumptions through a *reductio* proof. However, deciding which of the assumptions is most likely false is tantamount to choosing a particular solution to the problem of mental causation for which some background argument is required (for an informal explication of these *reductio* proofs, cf. Sturgeon, 1998, pp. 414–432; Harbecke, 2008, 29–31). The four resulting general positions are described in the following subsections.

Rejecting (P1): Epiphenomenalism or Parallelism

There are actually two related theories of mental causation that are based on a rejection of (P1). The first one is an epiphenomenalist position. The second is a parallelism, sometimes also called a 'dual explanandum strategy.'

An epiphenomenon is a phenomenon that is instantiated alongside, or that co-occurs with, some primary phenomenon. In the context of mental causation, the term epiphenomenon is intended to describe phenomena that are caused, but that do not cause anything themselves. In this sense, epiphenomenalism is the view that mental states occur as effects of physical effects and perhaps even regularly alongside certain neural correlates. However, mental causation is illusory. Only the physical events correlated with mental events do real causal work.

One of the earliest explicit defenses of this position was developed by Huxley (1893), who claimed that human beings are nothing but 'conscious automata.' Huxley's view was influenced by the studies of a certain Dr. Mesnet of a French soldier who had suffered severe brain injuries during the Franco–Prussian War of 1870. The soldier was able to carry

out various everyday tasks such as washing and dressing himself, eating whatever was set before him, going to sleep at regular hours, etc. However, he seemed completely unaware of environmental influences such as noise and odor, even of pins run into his skin. As Huxley was not ready to reject dualism, he concluded on the basis of such observations that physical states outplay mental states with respect to bodily behavior.

In the twentieth century, most philosophers no longer believed in substance dualism. The more recent epiphenomenalist positions therefore focus on the causal efficacy of mental types. The central idea driving these positions is that mental events are identical to physical events, but these psychophysical events do not cause anything in virtue of the mental properties they instantiate (cf. Bieri, 1992; Walter 2008a,b; note that the rejected premise (P1) must then be rephrased as 'some mental properties are causally relevant for some physical properties,' and (P2)–(P4) must be rephrased accordingly). The arguments for this position point out that the physical types of the relevant events are already sufficient for the corresponding behavioral effects and the mental types are at best redundant. Others state that mental properties are essentially external, or holistic, in character. Since causation is a local matter, mental properties cannot have causal relevance (cf. Fodor, 1987, pp. 27–54).

A special kind of epiphenomenalist theory is based on an argument for the possibility of 'Zombies' and the existence of qualitative experiences. Zombies are creatures that are just like humans physiologically, but that do not enjoy any conscious experiences. If Zombies really are possible, then mind and body are separable in principle, and the mind is not identical to the physical. But also then the mind does not contribute anything to what goes on in the world and, hence, is epiphenomenal (cf. Kripke, 1972; Jackson, 1982, 1986; Chalmers, 1996).

Counterarguments against epiphenomenalist positions have emphasized that denying mental causation would falsify almost everything humans believe about themselves and their environment. Since such a massive misunderstanding is not plausible in light of the success of our explanations of other people's behavior as well as our own, the existence of mental causation should be considered an undeniable fact (cf. Baker, 1993; Burge, 1993). Moreover, epiphenomenalism is in conflict with the widely accepted Eleatic principle in metaphysics, which is meant to rule out extravagant ontologies. The principle demands that nothing exists that does not have a causal effect some time and somewhere. Hence, if epiphenomenalism denies the causal powers of the mental, it thereby denies the very existence of mental phenomena.

The above-mentioned parallelist, or dual explanandum, strategies typically deny that mental phenomena cause physical phenomena, but claim that mental phenomena only cause further mental or other nonphysical phenomena. An early version of parallelism is found in Leibniz' *Monadology*. In Leibniz' view, God has designed the world in a way that lets mental and physical substances develop in time without interaction. Just as two clocks displaying exactly the same time may appear to be magically connected, the mental and the physical run parallel in complete harmony with another, but psychophysical interaction is an illusion.

More recent approaches argue that mental causation takes place only within the level of the mental (cf. Gibbons, 2006) or that ascriptions of mental causes typically cite different entities as effects than do causal explanations of bodily behavior (cf. Hornsby, 1986). Some compatibilists are also drawn toward a more complex kind of parallelism (cf. Section New Compatibilism and Harbecke, 2008, Chapter 3). These modern theories reject mental substances and locate mental causation on a type level. A vibrant debate has developed over the question whether such approaches are viable (cf. Kim, 2003; Harbecke, 2010; Harbecke and Atmanspacher, 2012).

Rejecting (P2): Interactionism

Denying (P2), i.e., the causal completeness of the physical, has become known as an 'interactionist dualism,' under which the position defended by Descartes should be subsumed (cf. Section A Brief History). Today only few philosophers subscribe to substance dualism, among which are Swinburne (1994, 1997) and Foster (1991, 1994). One argument brought forward by these modern dualists points out that the folk perception of matter as impenetrable and persistent is false. The physical sciences of today say little about what material things are in themselves. Rather, physics states only relational properties of physical entities. As a consequence, it is in principle possible to construct two observationally equivalent theories of our world T_1 and T_2, where T_1 describes the nature of all fundamental particles as physical and T_2 makes the same predictions but describes some of the fundamental particles to be of a mental nature. Hence, substance dualism is reasonable even in light of modern science. A second argument for interactionism builds on the conceivability, and therefore possibility, of a situation in which a conscious being survives the destruction of its body. The possibility implies that, already when the body and mind coexist, they are nonidentical.

The two general arguments have drawn criticisms concerning their validity as well as their motivation. In particular, the road from conceivability to possibility has been called into question (cf. Hill, 1997). It should also be noted that, even if the argument for substance dualism is correct, it is still not clear why then mental causes should have an influence on the physical domain.

That it is possible to challenge (P2) even without subscribing to any kind of substance dualism has recently been argued for by authors such as Hendry et al. (2006), Bishop (2008), and Bishop and Atmanspacher (2011). Whether these scientific arguments against the completeness of physics provide good reasons for mental-to-physical causation is still subject to an ongoing debate.

Rejecting (P3): Identity Theories

The rejection of (P3) is a popular move made by identity theorists. The claim that not all mental events are physical has been held in combination with a type nonidentity, or 'nonreductionist' (Davidson, 1970, 1993; Fodor, 1974, 1997; MacDonald and MacDonald, 1986) as well as a type identity, or reductionist (Lewis, 1966; Kim, 1998) theory.

One version of a nonreductionist token-identity theory is anomalous monism as promoted by Davidson (1970, 1993).

Davidson's main claim is that there are no psychophysical laws since mental types are holistically individuated whilst physical types are not. And since lawhood is essential for causation, mental events can only cause physical events qua being physical. As a second version, functionalist theories of the mind usually point out that mental types are multiply realizable by, and therefore not identical to, physical kinds (cf. Putnam, 1967, 1975; Fodor, 1974). Only mental tokens are identical to physical tokens.

Critics of functionalism such as Honderich (1982) and Kim (1993a,b) have attacked nonreductionist identity theories on the basis of the insight that events always cause further events in virtue of some of their properties. But if mental events do not cause any physical events in virtue of their mental properties and only in virtue of their physical properties as Davidson claims, then the token version of the identity theory does not provide a convincing theory of mental causation despite its rejection of (P3). Moreover, functionalism has been attacked on the grounds that mental kinds are always screened off by physical kinds with respect to their alleged physical effects (cf. Kim, 1979, 1985, 1998, 2003).

In light of these conclusions, several authors have tried to demonstrate that, contrary to initial appearance, mental properties are reducible to physical properties. The idea is that a reduction always preserves the ontology as well as the causal relevance of mental properties. Most prominently, Kim (1998, 2005) has promoted a technique to identify mental with physical properties, which has become known as 'functional reduction.' The original idea goes back to Lewis and Ramsey (cf. Lewis, 1966, 1972, 1979). According to this strategy, mental properties should first be defined wholly in terms of their inputs and outputs; i.e., they should be functionally construed. In the second step, the physical properties that have exactly the same inputs and outputs should be identified. The third step consists of the identification of the mental and the physical properties on the basis of their functional resemblance.

If things go well, for every mental property, precisely one physical property satisfies the functional definition. However, since it may well seem possible that a long list of physical properties all satisfy the same functional description definitional of a single mental state, it is unclear whether Kim gets any further than the token-identity theorists. To answer to this worry, some authors have tried to develop ways of preserving the mental ontology even in light of multiple realization. For example, Bickle (1998) argues that sometimes even reduction on disjunctive properties can be ontology-preserving. In contrast, Esfeld and Sachse (2007) try to demonstrate that with the introduction of mental subtypes it is possible to attain bijective reductions.

Rejecting (P4): Overdeterminationism

By applying a *reductio ad absurdum* inference against (P4), one accepts an overdeterminationist position, according to which mental causes, if they are causes of physical events at all, are always redundant causes. One version of this account has been developed by Loewer (2007). The author accepts that every physical event has a sufficient physical cause, but argues that certain mental events are counterfactually necessary for some physical events. This conclusion is then taken to establish at least a 'light' version of mental causation. As a second example, Bennett (2003) has explicated a counterfactual test for genuine overdetermination, which is a causation of a single effect by two counterfactually independent causes. Since mental events are typically not counterfactually independent of the physical causes of their putative effects, the test shows that the overdetermination described in the context of mental causation is of an unproblematic kind and should therefore be accepted as real.

Other authors such as Mills (1996) and Sider (2003) have critically reviewed the metaphysical principle ruling out a genuine systematic overdetermination of physical events. Mills demonstrates that the determining role by mental events becomes visible in counterfactual contexts, whilst Sider shows that systematic overdetermination is not in itself an incoherent assumption.

Recent Developments

Two main topics have been at the focus of the recent debate on mental causation. The first one has been described as a 'new compatibilism' in the sense that it strives to make a psychophysical nonidentity and mental causality compatible. The second one has focused on the implications of the interventionist theory of causation for the case of mental causation. This section provides a brief overview on both topics.

New Compatibilism

The core idea that unifies several approaches under the term new compatibilism is that mental and physical phenomena are neither identical nor wholly distinct. The idea is implicit in Yablo (1992a, 1992b), where the relation between mental and physical events is described as 'metaphysical determination.' Pereboom and Kornblith (1991) have promoted the idea that mental phenomena are 'nonidentical but wholly constituted' by physical phenomena. The idea surfaces also in the works of Bennett (2003), Shoemaker (2001), and Harbecke (2008).

All of these contributions take the fact that mental and physical events are not wholly distinct to imply that they cannot causally compete with another. This result corresponds to intuitions we have about colors such as 'red' and 'crimson,' which are also very intimately related but do not compete for causal relevance. For instance, it would be quite absurd to claim that the redness of the flag was not the cause of the bull's chasing it, because the crimsonness of the flag was already sufficient for the chase. It may seem as though the new compatibilists reject (P4) and should therefore be described as overdeterminationists. This, however, is not the case for those new compatibilists who combine their view with a principle of causal proportionality. According to this principle, causes must resemble their effects in specificity and detail. Hence, complex microphysical events do not qualify as proportionate to macro events such as a walk to the ice cream store, stopping a car, etc. The intuition is that some mental events will in fact turn out proportionate to events of this kind. This result would mean that the new compatibilists either reject (P1) (cf. Section Rejecting (P1): Epiphenomenalism or Parallelism), or hold onto premises (P1)–(P4) but identify an ambiguity in

the premises with respect to the word "physical" (cf. Sturgeon, 1998).

Interventionism and Mental Causation

Some authors have argued that interventionist theories of causation shed new light on the problem of mental causation. According to interventionism, causal relations can be analyzed and assessed only with respect to a causal model. And there are good reasons to believe that mental events (represented as mental variables in a model) satisfy all the relevant causal criteria with respect to some physical events in some validated causal models. That is, in some models an independent intervention on a mental variable induces a change in a physical variable (cf. Menzies, 2008; Menzies and List, 2010; Weslake, 2009; Raatikainen, 2010; Woodward, 2008).

The problem with this observation seems to be that any model that qualifies mental variables as causes can be extended into a model in which the mental variables fail to be causes. This is due to the widely accepted assumption of a psychophysical supervenience (cf. Kim, 1984), according to which any mental variable necessarily depends on, and is determined by, some physical variable. In this case the requirement of an independent intervention on the mental variables is no longer satisfied (cf. Baumgartner, 2009, 2010). A potential reply would be that the original toolbox of interventionism was not designed to include metaphysically related variables into the model and that, consequently, the putative violation of the independent intervention requirement is vitiated (cf. Woodward, 2011). Whether this reply is acceptable or whether it is merely ad hoc is the topic of an ongoing debate.

Abstract

Epidemiology in the field of mental disorders is the study of their distribution in populations and of the risk factors associated with their onset and course. The article summarizes considerable advances in terms of number of studies, their scope, the degree of methodological sophistication, and their linkages to the allied disciplines and points to deficits with regard to longitudinal and causal analytic epidemiological studies. These designs are of core importance to understand the natural course, the longitudinal stability of subsymptoms, and comorbidity associations as well as core vulnerability and risk factors for the onset and persistence of mental disorders.

Epidemiology in the field of mental disorders is the study of their distribution in populations and of the risk factors associated with their onset and course. During the past decade, there have been considerable advances in terms of number of studies, their scope, the degree of methodological sophistication, and their linkages to allied disciplines. There is now increased national and international collaboration on the basis of more stringent methodologies and designs, which allow for powerful coordinated cross-national reanalyses with regard to prevalence, age of onset, disability, and demographic correlates (e.g., World Mental Health Survey Initiative (Kessler et al., 2011)). However, deficits remain, particularly, with regard to longitudinal and causal analytic epidemiological studies. These designs are of core importance to understand the natural course, the longitudinal stability of subsymptoms, and the nature and development of comorbid constellations as well as core vulnerability and risk factors for the onset and persistence of mental disorders. Such studies can also provide more convincing evidence for the clinical and nosological validation of mental disorders in terms of their prognostic value and stability, family and genetic findings, as well as laboratory findings, ultimately allowing for a sharper genotypic and phenotypic classification. Beyond the continuing need for descriptive epidemiological studies that play an increasingly important role in basic clinical and public health research, the key challenge of epidemiology will be to gain a deeper understanding of how multiple risk and vulnerability factors interact over the life span in producing one or multiple mental disorders over brief or longer periods of time.

Epidemiological methods provide tools to conduct research with regard to the distribution of mental disorders in populations, their impact, and their etiology, and serve as the basis of outcome studies, clinical trials, and public health research. Key requirements of epidemiological studies are (1) the definition of the target population (e.g., total population or representative samples of a region or a country, or representative fractions thereof); (2) explicit, reliable, and valid criteria for disorders or what constitutes a case (e.g., symptoms or syndromes); (3) explicit, reliable, and valid criteria for variables and factors that might be associated with a disease (i.e., gender, social class, genetic factors, infectious agents), and (4) use of epidemiological methods for measuring outcome occurrence (e.g., *prevalence*, defined as the proportion of individuals affected by a particular disorder at a specified time period or point in time, and *incidence*, defined as the number of new cases among persons in a population, who were initially free from the disorder and developed the disorder over a given period of time, such as a lifetime, 1 year, or 30 days), and for measuring associations (risk and protective factors), and impact (i.e., course of illness, associated impairments, and disability). Epidemiology can be divided further into two interrelated orientations and methodologies, namely, *descriptive epidemiology*, aiming at measuring the extent of mental disorders in the community, and *analytic epidemiology* (e.g., longitudinal cohort designs, case–control studies), that focuses on understanding the natural course and etiology of mental disorders. Epidemiology offers some unique and promising research strategies for describing and clarifying the nature, etiology, course, and outcome of mental disorders, because patients in treatment settings usually represent a small and highly selective segment of the full spectrum of mental disorders. Thus, findings for risk factors and prognosis might be biased by selection biases as well as the severity of the studied condition.

Originally, epidemiology and epidemiological research designs were developed to study chronic and infectious diseases, and have only been adapted slowly for use in mental and behavioral disorders since the 1950s, largely due to the initially controversial status of past diagnostic classification systems for mental disorders. The complex manifestations, poorly understood etiologies, and variability of the course of mental disorders, in addition to their previously low diagnostic reliability, were often difficult to capture in basic epidemiological designs. This difficulty was particularly true for studies involving one or two points in time (e.g., cohort studies). In addition, risk factors for mental disorders can be as difficult to conceptualize and assess as variables of relevance for mental disorders. Despite early difficulties, these problems have been partly overcome in recent years.

Strongly related to the introduction of more reliable and valid classification systems for mental disorders, based on explicit criteria and operationalized diagnoses in 1980 (APA,

Table 1 Epidemiology of mental disorders in the first decade of the twenty-first century

Progress	*Deficits*
Broad availability of large-scale general population studies (prevalence, sociodemographic correlates, comorbidity, age of onset)	Limited number of studies in children, adolescents, and the elderly
More comprehensive diagnostic spectrum (e.g., childhood and adolescent disorders, somatoform disorders, eating disorders, sleep disorders, comorbidity with somatic conditions)	Incomplete coverage of diagnoses (deficits: psychotic disorders, personality disorders)
Increasingly sophisticated sampling, design, and statistical procedures	Few prospective longitudinal, multiple wave studies
International collaboration (joint reanalyses on prevalence, risk factors, comorbidity)	Explorations of thresholds for and boundaries between disorders
Documentation of associated impairments and disabilities	Assessment of diagnosis-specific disability and impairment
Crude documentation of poor recognition and intervention	Service utilization and need assessment
Improvements in diagnostic instruments and contributions to psychopathology and diagnostic classification	Assessment of natural course and persistence, developmental pathways, and trajectories
Increasing number of prospective longitudinal and family genetic studies, mostly in children and adolescents: contributions to nosological research (identification of vulnerabilities and risk factors) and natural course	Linkage to genetic research and neurobiology, developmental continuity of adult mental disorders

1980) and the increasing availability of structured and standardized diagnostic assessment instruments, the past three decades witnessed an unprecedented progress in epidemiological research on mental disorders. The field has tremendously advanced in terms of the number of studies, their scope, the degree of methodological sophistication, and their linkages to allied disciplines such as psychology, neurobiology, and sociology (see **Table 1**). What started in the 1950s as a scientifically problematic and quite restricted area of 'psychiatric epidemiology' (Robins, 1992) has now reached firmer ground and opened up new perspectives.

Descriptive Epidemiological Findings

Starting with the landmark Epidemiological Catchment Area program in the early 1980s (Robins and Regier, 1991), increasingly sophisticated large-scale studies in the general population have made it evident that mental disorders are very frequent disorders of the brain, affecting more persons than not over their life course. These studies have also highlighted the correlates and the variability in the manifestations of disorders of emotion, cognition, physiology, and behavior, demonstrating that mental disorders are not as uniform as previously believed in terms of their risk factors, courses, outcome, associated disabilities, and impairments.

Prevalence and Correlates of Mental Disorders in the Community

Cross-sectional community surveys such as the US National Comorbidity Survey Replication (NCS-R) (Kessler et al., 2012) and similar studies in other countries around the world (see World Mental Health Survey Initiative, Kessler et al., 2011) have estimated the lifetime rates for mood, anxiety, impulse control, and substance use disorders alone to range between 20 and 48% with anxiety disorders being the most common group in most countries followed by mood disorders and substance use disorders (Wang et al., 2011). The projected estimated lifetime risk up to the age of 75 years is even higher with rates up to 56%. Prospective longitudinal studies that examine mental disorders in the same cohort at multiple time points provide evidence that cumulative rates are even considerably higher (Beesdo et al., 2010; Copeland et al., 2011; Moffitt et al., 2010). The 12-month prevalence estimates vary around 10–14% for anxiety, 5–8% for mood, and 2–4% for substance use disorders, in spite of differences in coverage of diagnoses, design, and cultural setting (Kessler et al., 2011; Wittchen et al., 2011).

Similar convergent evidence has also become available from these studies with regard to sociodemographic correlates and impairment. For example, (1) the majority of people affected by a mental disorder usually report the onset of their condition before adulthood, largely due to a predominant early onset of anxiety disorders (childhood or adolescence) and substance use disorders (in adolescence), whereas depressive disorders occur over the whole life span; (2) females are 2–3 times more frequently affected by various depressive and anxiety disorders; (3) males develop substance use and antisocial personality disorders more frequently; (4) low social class has not been confirmed consistently as being associated with the onset of mental disorder in all countries; and (5) the presence of mental disorders has been found to be associated consistently with increased rates of disability and impairment days, which vary by the type of disorder and comorbidity.

The World Mental Health Survey Initiative (Kessler et al., 2011) also revealed that even in developed countries only about half of those with the most severe disorders receive any treatment, irrespective of appropriateness in terms of type, dose, and duration. The vast majority of cases were cared for in the primary health care sector, with only few receiving treatment by mental health specialists. Overall, only about one-fourth of all cases in developed countries receive any minimally adequate treatment. A further disturbing finding is the fact that the majority of patients delay many years after the onset of their disorder before getting treatment. It is not entirely clear to what degree these low treatment rates are due to patients' poor help-seeking behavior, structural barriers in the health care system, or health service providers' lack of recognition and diagnostic skills. However, the fact that low treatment rates are not confined to countries that do not cover health care and treatment cost by insurance plans suggests that there are many reasons for this problem.

Another important finding of studies is that, even in community samples, a high proportion of subjects suffer from more than one mental disorder. In the NCS-R (Kessler et al., 2005a), the majority of people with one lifetime mental disorder had comorbid conditions as well; overall, 17% of the population had three or more lifetime conditions. Among those with a 12-month diagnosis, 22% had two and 23% had three or more diagnoses (Kessler et al., 2005b). Most frequent patterns of comorbidity were among anxiety, mood, and substance use disorders. The consistency of comorbidity findings across studies has made it clear that comorbidity is a fundamental characteristic of most mental disorders. Comorbidity has been shown to be neither simply an artifact of random association of frequent disorders nor influenced by help-seeking behavior or methodological aspects of the studies (Wittchen, 1996). Comorbidity has specific effects on the degree of suffering as well as the likelihood of seeking professional help. Research into the meaning and the implications of comorbidity has received considerable attention during the past decade resulting even in proposals for a new simplistic 'meta-structure' of mental disorders, which, however, insufficiently reflects the developmental variations in the expression of psychopathology (Wittchen et al., 2009).

Prevalence of Mental Disorders in Primary Care

Although large-scale comprehensive studies about the prevalence of the range of mental disorders in primary care are lacking, there is considerable evidence from international collaborative primary care studies on selected disorders (Üstün and Sartorius, 1995) that these disorders are highly prevalent in primary care settings around the world: point prevalence estimates for depressive disorder range between 6 and 11%, and those for anxiety disorders range between 4 and 10%, with some more recent studies indicating even higher rates (Ansseau et al., 2004). Such studies have also revealed that mental disorders in primary care are usually poorly recognized and rarely treated (Wittchen et al., 2002). Only every second case is recognized, and of those recognized, only one-third receives some type of state-of-the-art treatment.

The Burden of Mental Disorders

Along with the increased emphasis of epidemiological research on the role of general and diagnosis-specific disabilities and impairment, community studies have also been able to demonstrate the substantial burden that mental disorders have on the subjects' lives, social functioning, and interpersonal environment. Based on available epidemiological data, the Global Burden of Disease study (Murray and Lopez, 1996; Murray et al., 2012; Vos et al., 2012) showed that the burden of mental disorders has been underestimated greatly. Mental and behavioral disorders accounted for almost one-quarter of all years lived with disability (YLDs) and have increased by over one-third from 1990 to 2010. Major depressive disorders alone caused 63 million YLDs and ranked number 2 among all causes across all ages (**Figure 1**), and number one for ages 10–29 years. Anxiety disorders, drug use disorders, alcohol use disorders, schizophrenia, bipolar disorders, and dysthymia were also major causes of global YLDs. Given these numbers it is not surprising that a recent study on the cost of disorders of the brain in Europe in 2010 revealed that mental disorders result in tremendous costs (overall €461 billion in 2010), with mood disorders being the most costly condition of all disorders of the brain (Gustavsson et al., 2011). Indirect health care costs usually exceed direct health care costs for mental disorders because people are not able to work.

Progress and Unresolved Issues in Descriptive Epidemiology

Despite the fact that considerable progress has been made in the past two decades, descriptive epidemiological knowledge is

Figure 1 Global years lost to disability for the 20 most common causes in 1990 and 2010. COPD, chronic obstructive pulmonary disease. Source: 2013, Institute for Health Metrics and Evaluation. http://www.healthmetricsandevaluation.org/gbd/visualizations/gbd-arrow-diagram (accessed 19.06.13.).

still limited in various respects, given in particular that not all mental disorders have been investigated. Other areas with remaining deficits are (1) mental disorders in children, adolescents, and the elderly; (2) the dimensional and subthreshold characterization of mental disorders; (3) a more comprehensive identification of risk factors; (4) the range of associated disabilities; and (5) the use of health services with emphasis on national and cultural variations.

Coverage of Disorders

Epidemiological research has expanded in terms of the range of clinically significant psychopathological conditions examined, with increasingly more data becoming available for somatoform disorders, sleep disorders, and some forms of childhood disorders. Noteworthy deficits, however, still exist, particularly with regard to personality disorders and psychotic disorders. Each of these conditions merits considerable epidemiological attention from a public health, and even more from a pathogenetic perspective, because they have different onset and course characteristics, and are frequently comorbid. For example, somatoform disorders (i.e., pain disorders, hypochondriasis, somatization), which were shown to be highly prevalent conditions that start early in life and constitute a major burden on the health care system, have rarely been included in past community surveys. Similarly, sleep disorders, which rank high as a principal reason for primary care consultations, have only been studied in some community surveys. The unclear nosological status of these conditions may be responsible for this neglect. Obstacles to research on personality disorders and psychotic disorders are of a methodological nature because there are not sufficiently reliable and time-efficient assessment tools available.

For childhood conditions, the challenge lies in consensus regarding the appropriate choice of age-/developmental-stage-specific diagnostic assessments. Researchers must also concur on the degree to which multiple sources of information (i.e., parents and teachers) can be combined into one coherent strategy that mirrors the continuity from childhood to adolescent and adult mental disorders. Despite growing collaboration, there is still a remarkable division among investigators regarding epidemiological designs and methods used in childhood, adolescent, and adult mental disorder research. Inherent in this division is the issue of the developmental continuity of psychopathological features, which also touches partly on the ongoing controversy of dimensional versus categorical measures in epidemiological studies of mental disorders. Intensified research in this area is needed, especially because of evidence that most adult mental disorders begin in childhood or adolescence.

Subthreshold Conditions and Dimensional Approaches

With few exceptions, descriptive epidemiological evidence is based on a range of threshold diagnoses, assessed with diagnostic instruments, such as the World Health Organization (WHO) Composite International Diagnostic Interview (CIDI) or versions thereof (Kessler and Üstün, 2004; WHO, 1990). The reliance on categorical threshold diagnoses carries substantial risks of artifactual explanations (such as in comorbidity analyses) and fails to acknowledge the dimensional nature of most expressions of psychopathology. The *Diagnostic and Statistical Manual* (DSM)-IV (APA, 1994), as the most frequently used classification system in research into mental disorders in the past 20 years, made only a few attempts to derive discrete categories that are mutually exclusive and lead to a single classification of an individual. In fact, the system was intended to stimulate further development of research on the thresholds for and boundaries among disorders (APA, 1994). DSM-5 (APA, 2013) attempts to better resemble the rest of medicine by including the use of dimensional approaches (Kupfer et al., 2013) and it remains to be shown by future research whether this approach is a more optimal source for modifying diagnostic systems and 'to carve nature at its joints' (Regier et al., 2009).

Assessment of Disability and Need of Treatment

Over recent years, increasing recognition has emerged that diagnoses of mental disorders themselves cannot appropriately answer questions about the need for care, service utilization, and treatment match. Such domains are thought to be determined largely by the individual's functioning status and disability. Epidemiological studies from the beginning of the twentieth century have begun to provide more coherent and comprehensive information about service-related issues. However, reliable characterizations of diagnosis-specific degrees of disability with regard to various social roles is still scarce, as is sufficiently detailed data about help-seeking behavior, service utilization, and services needs (Regier et al., 1998). The WHO has conducted collaborative, systematic, conceptual, and psychometric developmental work to design a generic and practical instrument to assess health and disability levels across all diseases, including mental disorders (the World Health Organization Disability Assessment Schedule 2.0) (Üstün et al., 2010). This instrument is based on the International Classification of Functioning, Disability and Health and can be used in the general population or in clinical settings to provide a better basis for need assessment in the area of treatment. In the context of the Global Burden of Disease study developed estimates such as YLDs (prevalence of the condition multiplied by the disability weight for that condition) and disability-adjusted life years (DALYs; a summary measure of YLDs and years of life lost (YLLs) due to premature mortality) (Murray et al., 2012; Vos et al., 2012) clearly indicate great challenges on the health care systems due to the rising burden from mental and behavioral disorders and the urgent need to develop effective and affordable strategies to deal with this rising burden.

Assessment Instruments and Diagnostic Classification

Population studies and methods-related epidemiological work have been instrumental in the improvement of diagnostic classification systems for mental disorders. Reliable symptom and diagnostic assessment instruments of mental disorders have been created for use in epidemiology and clinical research. This work has not only significantly influenced the content and structure of clinical instruments, such as the Structured Clinical Interview for DSM-IV (First et al., 1997) and the Schedules for Clinical Assessment in Neuropsychiatry (SCAN) (Brugha et al.,

1999b), as well as nonclinical tools such as CIDI (WHO, 1990; Kessler and Üstün, 2004), but also played an important role in the revision processes of diagnostic classification systems.

Yet these conceptual models of mental disorders are not, and have never been, a paragon of elegance, and they have also not resulted in sufficiently neat and crisp classification systems that match basic research findings and clinical management and decision making. The introduction of these operationalized and descriptive manuals has resulted in greater diagnostic reliability and consistency in the use of diagnostic terms around the world. In particular, they have been a key prerequisite for epidemiological progress. However, major problems (i.e., thresholds, overlap, and comorbidity), which remain a source of significant dissatisfaction and controversy, will require extensive future work.

At the center of this agenda is the need for convincing clinical and nosological validation in terms of prognostic value and stability, family and genetic findings, and laboratory findings for almost all mental disorders, allowing a sharper genotypic and phenotypic classification. Current diagnostic classification manuals (DSM-5 and International Classification of Disease-10) deliberately do not contain mutually exclusive diagnostic categories in order to simulate research inquiries into diagnostic boundaries and thresholds – a valuable target for epidemiological research. Consensus is lacking on how to tailor appropriate psychopathological assessment instruments that are able to address such threshold issues appropriately. Further, despite the substantial scientific exploration and examination that went into instruments like the CIDI (WHO, 1990) and versions thereof (Kessler and Üstün, 2004) or the SCAN (Brugha et al., 1999b), some basic problems of reliability and validity inherent in the assessment of some mental disorders are yet unresolved.

At the center of discussion is no longer the traditional question of whether to go for categorical or dimensional, but rather to what degree and for which psychological conditions 'clinical judgment and probing' should be regarded as a mandatory core element. Empirical evidence needs to be gathered to determine which diagnostic domains and clinical instruments are superior to fully standardized instruments, such as the CIDI, which try to identify explicitly the latent variables behind the vagueness of clinical judgment. Progress in the resolution of this issue will also ultimately offer more appropriate strategies in resolving the 'gold-standard' question of the optimal strategy for validating epidemiological instruments (Brugha et al., 1999a; Wittchen et al., 1999).

Longitudinal Studies and Causal Analytic Epidemiology

Several costly large-scale prospective longitudinal studies have become available in various countries (e.g., Early Developmental Stages of Psychopathology Study, Great Smoky Mountain Study, Dunedin Multidisciplinary Health and Development Study) that have significantly contributed to improved knowledge about the patterns of incidence, the natural course, longitudinal stability of symptoms, and comorbidity associations, as well as vulnerability and risk factors for the onset and persistence of mental disorders particularly in children, adolescents, and young adults (overview in Beesdo et al., 2009). However, the 'causal risk factors' status (Kraemer et al., 1997) has not yet been established for most putative risk factors of mental disorders and there is limited insight into specific mechanisms and potential moderators and mediators (Kraemer et al., 2001).

There is strong evidence from studies with a longitudinal component that the majority of people affected with a mental disorder have had the first onset in childhood or adolescence, rarely remit spontaneously, and have a substantially increased risk for a number of temporarily secondary psychopathological complications (Beesdo et al., 2010; Copeland et al., 2009; Gregory et al., 2007). These developmental pathways – reflected in cross-sectional studies as co- or multimorbidity – are associated with an increasing degree of psychosocial dysfunctions and disability and seem to indicate the existence of critical trajectories for certain types of disorders that are potentially promising targets for interventions. Testing the effectiveness of specific interventions and the long-term outcomes on a broad, population-based level might not only be crucial from a public health perspective but also have significant value for improved causal models.

Prospective longitudinal studies have provided a substantial body of evidence with regard to partly diagnosis-specific and partly general risk factors for many disorders (e.g., Beesdo et al., 2010; Moffitt et al., 2007; Wittchen et al., 2000). Well-established risk factors include a family history of mental disorders, the effect of threatening or stressful disruptions in the individuals' immediate social environment, childhood loss, abuse, and trauma. There is also further evidence for more complex interactions: family genetic factors may enhance the effects of loss events, patterns of symptom progression from preceding early anxiety disorders relate to the risk of developing secondary depression, and certain childhood temperamental traits increase the risk of subsequent mental disorders. What remains, however, is the large challenge of completing the complex vulnerability–stress interaction, and understanding how vulnerability and risk factors from formerly competing paradigms interact with each other in specific disorders or groups of mental disorders.

Linking Epidemiology Closer to Clinical and Basic Neurobiological Research

The limitations of convenience samples from clinical and other settings for etiological and pathogenic research have been recognized. Limitations include the risks of artifactual findings, the over- and underestimation of effects, confoundation by comorbidity, and the impossibility of establishing risk factors for first onset of a disorder. Prospective longitudinal studies and causal analytic designs in representative population samples are of key importance to overcome these limitations. A requirement for such designs is a comprehensive evaluation of the epidemiological triad of host (i.e., genetic variables or temperamental predispositions), agent (life stage transitions or life stress), and environment (social processes or environmental agents). A considerable challenge for such studies is the identification of how and when certain environmental factors potentiate or protect against genetic and biological vulnerability factors. Neuroscience, and in particular, genetic research,

is likely to be essential for future understanding of the etiology and pathogenesis of mental disorders, and ultimately a better genotypic classification. The complexity of longitudinal designs, and the time and costs involved, are substantial; however, emerging findings begin to shape a better understanding of the relevant developmental pathways of specific mental disorders and their interrelationships among each other (comorbidity) (see **Table 2**).

Family and other genetic studies have demonstrated convincingly that an individual's genetic makeup is an important factor in determining vulnerability for almost all mental disorders (Merikangas, 1999; Schreier et al., 2008). Methods of genetic epidemiology for studying risk factors and etiology of familial diseases appear to be the most promising ways to unravel the complex mechanisms through which genes exert their influence. The integration of population genetics and epidemiology is critical for determining the attributable risk of particular deoxyribonucleic acid markers for disease as well as how environmental conditions increase or reduce expressions of genetic vulnerability. Such studies might be directed at states or traits conferring susceptibility. In the first decade of the twenty-first century, initial findings from such types of genetic epidemiological studies emerged identifying some of those genetic factors that place individuals at increased risks for disorders such as substance dependence, anxiety, and depression (Caspi et al., 2003; Polanczyk et al., 2009).

Mental Disorders Are the Core Health Challenge of the Twenty-First Century

The increasingly broad and methodologically improved epidemiological database that has become available over the past decade has allowed not only for considerably improved estimates but also for a more comprehensive picture with regard to the diagnostic spectrum and age groups covered. The resulting prevalence findings and estimates of the burden of disease underline impressively that mental disorders must be considered the major health challenge of the twenty-first century, at least in developed countries (Wittchen et al., 2011). Since the 1980s, quite comprehensive, interdisciplinary mental health systems of providers have emerged in most industrialized countries. However, given the size of the problem of mental disorders it is evident that no system could afford comprehensive treatments for all affected persons. Epidemiological data are a key prerequisite for identifying deficits and problems in health care systems, and offering guidance in service planning and resource allocation. At a time of increasing numbers of effective pharmacological and psychological treatments, competing provider models for mental disorders, and tighter health care budgets, epidemiology can be expected to gain further importance, especially in highlighting the efficacy of interventions (see **Table 3**).

Core elements of need assessment are a reliable definition of a disorder, clearly defined associated disabilities, and existing effective interventions (taking into account both their limitations and modes of delivery). Nevertheless, despite the existence of many effective psychological and drug treatments shown to prevent disability, relapse, chronicity, and suffering for many mental disorders, few epidemiological studies are available that answer with sufficient detail core questions such as how many anxiety or depressive disorders were treated by psychiatrists, psychotherapists, or other types of providers; how many were treated by medication or some form of psychological treatment, or even treated at in- or outpatient institutions; how many in need are treated appropriately; and how many remain untreated. Instead, mostly crude data regarding rates of service utilization and unmet service needs are available that emphasize predominantly the role of primary care physicians. Even though the quite limited role and poor recognition abilities of primary care physicians for mental disorders has been noted repeatedly throughout the world (Üstün and Sartorius, 1995; Wittchen et al., 2002), it seems that traditional psychiatric epidemiology still seems to favor this model strongly. More comprehensive service utilization and need assessment strategies for specialist treatment and other interventions are neglected. Another unfortunate deficit in this field is its strong emphasis on so-called 'major mental disorders,' such as psychotic disorders, as opposed to 'minor and neurotic disorders.' Although this oversimplified dichotomy has clearly outlived its usefulness and scientific justification since the 1980s, many health care utilization and needs surveys still overemphasize major morbidity, neglecting what are actually the most prevalent and persisting 'minor morbidity conditions,' which cause by far the greatest financial burden of all disorders (Murray et al., 2012; Vos et al., 2012). Current

Table 3 Types of questions related to comprehensive need assessment

Stepwise questions	*Epidemiological activity*
What is a case?	Prevalence, incidence
What do patients need?	Subjective/objective
Do patients get what they need?	Inappropriate/insufficient use and service delivery
How can structure and process of services/treatment be improved?	Evaluation of changes, stepwise planning of improvements

attempts that merely link diagnosis with measures of disability in order to improve need assessment (see above) might not solve this critical problem. Rather, they might result once again in an inappropriately strong emphasis on the most severely ill, neglecting those in earlier stages of their illness process who might profit most from modern treatment methods.

The challenge for epidemiology on a cross-national and international basis lies in a systematic comparison of such competing models. Development of appropriate assessment instruments for use in epidemiological studies to identify advantages and disadvantages of each of these perspectives, in terms of legal, cost, comprehensiveness, and effectiveness issues, has been identified as a necessary first step (Jagger et al., 1998). Current perspectives on this issue seem to overemphasize two search strategies: the development of reliable and valid measures of disability (Regier et al., 1998; Üstün et al., 2010), and the search for other 'marker' variables of those in greatest need or the 'most severe.' This perspective might fall too short. In search of improved approaches for comprehensive need assessment and evaluation, future epidemiological research should additionally emphasize: (1) a more comprehensive assessment of help-seeking behaviors that covers the full spectrum of professional providers in the respective country or region; (2) a wider coverage of types of interventions received, contingent on the availability of treatments in that country for that diagnosis; and (3) a detailed inquiry into perceived barriers to recognition and treatment.

Conclusion

In light of the ongoing rapid developments in neuroscience, clinical psychology, and psychiatry, as well as public health research, epidemiology can be expected to further play an increasingly important role in basic, clinical, and public health research of mental disorders. The key challenge will be to understand how multiple risk and vulnerability factors interact over the life span in producing a single or multiple mental disorders over brief or longer periods of time.

Abstract

The term mental health sits alongside the larger topic of mental disorder with which it overlaps while retaining a wider concept of general, including physical health, well-being, positive functioning, and the development and maintenance of interpersonal relationship functioning. The promotion of mental health depends in part on the prevention of mental disorder, a vital but largely neglected topic for which there are now promising signs of progress.

Introduction and Concepts

Mental health has been defined in several related ways. It describes a level of psychological well-being, or an absence of a mental disorder; the World Health Organization defines mental health as "a state of well-being in which the individual realizes his or her own abilities, can cope with the normal stresses of life, can work productively and fruitfully, and is able to make a contribution to his or her community." Most recently, the field of 'global mental health' has emerged, which prioritizes equity in mental health for all people in the world. From the perspective of 'positive psychology' or 'holism,' mental health may include an individual's ability to enjoy life, and create a balance between life activities and efforts to achieve psychological resilience. Mental health can also be defined as an expression of emotions, and as signifying a successful adaptation to a range of demands. Mental well-being relates to a person's psychological functioning, life-satisfaction and ability to develop and maintain mutually benefiting relationships. Psychological well-being includes the ability to maintain a sense of autonomy, self-acceptance, personal growth, purpose in life and self esteem. Staying mentally healthy is more than treating or preventing mental illness (Tennant et al., 2007).

When originally introduced, the term 'mental health' was intended to be interpreted literally. Its originators were primarily motivated by the wish to promote mental health and tackle any obstacle to this aim (Bertolote, 2008). This article is devoted to an overview of understanding and evidence about mental health and how it can be achieved or sustained within human populations. We focus on the historical, conceptual, policy, population, and intervention evidence underpinning mental health. Historically, the term mental health owes its origins to the mental hygiene movement developed by Clifford Biers in nineteenth-century America (Bertolote, 2008) based on his personal experiences of mental hospital admissions. Its initial purpose was to promote early diagnosis and treatment and humane care for psychiatric patients but notably it expanded to the wider community, policy and government embracing "not a single patient, but a whole community; and it considered each member of that community as an individual whose mental and emotional status was determined by definite causative factors and whose compelling need was for prevention rather than cure." However, the eventual, gradual and welcome embrace of psychiatry and of mental disorder officially at national and international levels (for example, the World Health Organization) soon adopted the term 'mental health' with little more than a side reference to well-being, prevention and promotion.

Conceptually, it may also be unhelpful to keep apart the terms mental health and mental disorder. The trouble is that people perceive, think and fear, in categories and prefer the language of 'mental breakdown' to that of 'increasing anxiety or depression.' Evidence suggests that the two represent different ends of a smooth distribution (Melzer et al., 2002). At its very simplest, a depression score that is low or zero can be described as health, but at or above an agreed threshold as disorder. Guidelines on treating depression now advocate a stepped care approach in which investigation and intervention are tailored to severity, chronicity (and risk). This approach can be seen as replacing earlier binary guidance hinging on whether or not a patient meets an all or nothing set of diagnostic criteria, with all resources being devoted to the latter only.

Achieving (or sustaining) mental health thus means avoiding or preventing mental disorder and to do the first arguably could result in the second although this has not yet been shown. This requires an understanding of normal development and of how psychopathology in its different forms unfolds, which we can describe and measure reliably in psychiatry although it is less understood. Any definition must also consider the terms mental health, mental well-being, and mental illness or disorder. But research suggests that mental well-being is not simply part of the mental health disorder continuum. Thus, although similar factors are associated with mental disorder and mental well-being, models that incorporate both together do not suggest that they are equivalent (Weich et al., 2011).

Mental Well-Being

The term mental health is gradually being over shadowed by the term mental well-being (perhaps because well-being appeals to policymakers and politicians and because they have allowed the term mental health to mean absence of mental disorder). Mental well-being (see also Subjective Wellbeing, Psychology of) is not just the opposite of mental disorder; evidence suggests that both states can coexist in one person or population subgroup. The same factors have also been shown to be associated with both states (Weich et al., 2011). Mental well-being

may also be said to be a predictor of and predicted by mental health. Mental well-being can be defined as the positive end of a spectrum that includes the concepts 'mental health' and 'positive mental health' (Weich et al., 2011). There are two broad (and complementary) traditions in conceptualizing well-being: the 'hedonic' and 'eudaimonic' approaches. The hedonic approach emphasizes happiness (pleasant affect, life satisfaction) whereas the eudaimonic approach (with origins in Platonic philosophy) emphasizes optimal psychological and social functioning (or 'flourishing') (Weich et al., 2011).

Measurement of well-being has often relied on single questions assessing aspects of mental well-being, for example, questions on calmness and energy or on distinct factors derived from measures of mental symptoms, as in the General Health Questionnaire and the mental health component of the Short Form (SF-36 and SF-12) (Ware, 1993), which is also used to measure the related concept of quality of life. Thus components and elements of well-being measures can include mental health symptoms, principally of anxiety and depression, but possibly including somatic symptoms such as sleep problems, pain, fatigue, low drive, sexual functioning disturbances. There may also be positive well-being items like feeling healthy, energetic etc. Well-being measures tend to extend further to social functioning items, possibly activity items (work, leisure, community activities). But purpose designed measures are now being developed, which should foster better research. A significant development in the measurement of mental health and well-being outcomes is the Warwick-Edinburgh Mental Well-being Scale (Tennant et al., 2007).

Mental well-being is beginning to be regarded by national governments for its economic importance because higher national income has not brought the better *quality of life* that many expected (Layard, 2010). Gross Domestic Product and National Accounts measure economic well-being according to an internationally agreed system, but they are increasingly seen as measuring only part of societal well-being (http://www.statistics.gov.uk/hub/people-places/communities/societal-wellbeing). Governments in Europe are, therefore, beginning to monitor trends in well-being. Specific measures have been developed that are used in repeat general population surveys that also keep track of possible determinants of well-being, economic prosperity, education and health outcomes, progress in housing and welfare policies.

Physical and Mental Health

In this section on health, we need to ask is the distinction between mental and physical health valid? There are many indications that such a distinction often should be questioned: the growth of research into the biological including genetic underpinnings of mental disorder as if such disorders were physical; the idea that, for example, taking time off from work for a spell of depression should be viewed as no different than taking time off for back pain, a viral respiratory infection etc.; and the often quoted contemporary health policy statement 'no health without mental health' (Prince et al., 2007). It has long been recognized in primary care that mental health problems often present initially as physical complaints. Epidemiologists are increasingly demonstrating that throughout the world physical and mental health are interrelated in research also showing that mental disorders are more likely to be associated with severe disability than are chronic physical conditions (Scott et al., 2009). Interestingly in the last decade depression has overtaken back pain as the number one medical reason for claiming work absence benefits in England.

Mental Disorder and Disorders from a Neurodevelopmental Perspective

If mental health is defined in part as the absence of mental and behavioral disorders it is important to move toward a seamless approach that takes into account phases of development (of psychopathology) across the full life course (Kingdon et al., 2010). Readers new to the subject will notice the puzzling but distinctive difference between current childhood and adulthood classifications of mental and behavioral disorders. Although the same conditions that appear in child classifications, for example, conduct disorder and autism, are recognized in adulthood, in practice they either acquire a different term, for example, antisocial personality disorder, or are rebranded, for example, asperger syndrome, learning disability. Definitions and defining boundaries also shift making empirical comparison, learning, and understanding more difficult. The problem probably reflects a lack of consensus on what underlies mental and behavioral disorders. A simple biological analogy may assist us, based on the growth of a tree (or any plant; see panel).

Biological cause	*Abnormality in tree or other plant*	*Mental disorder analogy*	*Possible cause*
Genetic	Stunted growth	Huntington's Chorea	Trinucleotide repeats on the HTT gene located on short arm of chromosome 4
		Autism	Mechanism highly heritable, complex and yet to be identified, understood
Environmental challenge, infection	Characteristic abnormal appearance	Delirium	Septicemia
		Depression	Adverse life events, long-term difficulties, child sexual abuse
Unknown	New disease with characteristic appearance	Dementia	Well-recognized brain pathology and neuroimaging findings but cause unknown

If genetically abnormal, growth will be stunted although that may not become evident until maturity has been reached. The human analogy, such as intellectual disability or a specific neurodevelopmental disorders such as autism can continue

into old age. Disease may impinge at any time in the absence of previous abnormality (for example, conditions that usually present first from puberty onward such as functional psychosis, depression etc.). Damage may also be caused by environmental challenge such as extreme weather (in the human example, adverse life events or long-term difficulties such as debt, prolonged physical and mental abuse). Growth, development, and aging may also be affected by climate, nourishment (analogous to unemployment, isolation caused by racism, stigma, prolonged conflict). In common across these examples is the notion of healthy and interrupted development. Any example, therefore, demands a consideration of prior level of development unless the condition is a clearly recognized example of a late onset disorder such as dementia where prior development has little effect on later outcome. And yet it is unusual for professionals looking at an adult needing an assessment or treatment to devote time and effort to obtaining information about prior growth and development and prior environmental exposure (parenting and other childhood social and learning experiences). The same argument goes for research to be meaningful and to cast a light on complex causal mechanisms that could help maintain mental health and lead to prevention of disorder.

Mental Health and Resilience, Personality, Resources, Social Support Networks, and Relationships, Social Structures and Social Capital

As well as well-being measures extending to social functioning, relationship quality, work, leisure, community activities, there is also ample evidence interconnecting these separate factors with mental health and with individual characteristics, which must form part of any account of mental health (Brugha, 2003). The complexity of such connections can be illustrated by a number of research findings. Anger or irritability, a sign of depression, is often directed at others and must partly explain the isolation that results from depression. An extensive literature connects adverse life events with many different types of mental disorder and probably interacts with temperament and personality (Goodyer, 2002). Associations involving the structure and composition of social relationships, including social network research, has been consistently shown to be important in mental health over many decades of research.

Not all findings are in the expected direction, however. Structural characteristics of communities including the relatively newer concept of social capital, represented by local characteristics such as the way that people contribute to a community, local crime rates etc., have been found to add little if anything to associations with mental health and disorder that include individual, household and family factors (Weich et al., 2003). There is also a disappointing lack of experimental research testing hypotheses linking such social factors to mental health or disorder. There is also the curious observation that interpersonal communication and relationship quality seems to underlie some of the effectiveness of psychological therapies. A recent systematic review of psychological therapy treatment trials concluded that most of the effect of therapy for adult depression is realized by nonspecific factors, with the results suggesting that the contribution of specific effects (cognitive behavioral, psychodynamic etc.) is limited at best (Cuijpers et al., 2012). It is hardly surprising, therefore, if interpersonal relationships (in this example between client and therapist) play a fundamental part in sustaining mental health as well as in defining it.

The Epidemiology of Mental Health and Mental Disorder

While 'rates' of mental health have not been specifically addressed in community surveys and studies, there exists an extensive literature on the frequency of mental disorders from which much can be approximately inferred (see also Health Surveys; Epidemiology, Concepts and Methods of). Earlier, we conceptualized mental health (and disorder) as being a dimensional construct within which it is useful to identify typologies or syndromes and to set thresholds, which expert consensus agrees to recommend as the dividing line between normality and clinically significant psychopathology. An unusual but compelling suggestion has been to describe common mental disorder in the population in terms of mean scores with normal or skewed distributions (Melzer et al., 2002), but most studies focus mainly on the frequency of types of disorders, which seems to appeal to policymakers, with dimensionality or severity receiving relatively less attention (Demyttenaere et al., 2004). The international setting for synthesizing such categorical disease or morbidity frequency information is the Global Burden of Disease study (GBD) (Murray et al., 2012), which ranks neuropsychiatric disorders such as schizophrenia and depression consistently above most physical causes of disability.

So how common is mental health (and or mental disorder) and are rates declining or increasing? The proportion of the child and adult population free of mental disorder has perhaps been most closely represented in estimates of common mental disorder as a dimension or score (Goldberg and Huxley, 1992; Meltzer et al., 1995). These two closely related approaches suggest that between 75 and 84% of the adult population enjoy mental health (or have few if any symptoms of common mental disorder). However, if one goes on to factor in problems associated with drug and alcohol dependency or misuse and lifelong factors such as intellectual disabilities these estimates fall further.

Good news is not exciting and does not grab media attention. No matter how many times good survey designs are repeated, using consistent methodology, seemingly well informed media discussions persist in presuming that rates of disorder in childhood and adulthood are rising. But as the GBD syntheses and high quality UK, Netherlands and US studies have shown rates are largely stable over recent decades (Murray et al., 2012). We do not know why. It is possible that a mix of positive and negative factors have been operating over time to increase and decrease rates. But as mentioned earlier, increased use of treatments for the commoner depressive disorders has not lead to any reduction in rates of these conditions (Brugha et al., 2004; Kessler et al., 2005). This has lead to calls to focus more on prevention because preventive approaches have had a positive impact on other forms of morbidity, globally (Murray et al., 2012).

Interventions to Promote Mental Health and Well-Being – A Research Method Note

Assessment of well-being and mental health outcomes has been considered above. Nonexperimental, observational research, whether to discover (or confirm) social, psychological, and environmental or genetic profiles associated with health states cannot finally determine causality and the means to improve health outcomes. Only experimental research designs involving controlled exposure to interventions can achieve this step forward convincingly, the gold standard experimental design being the randomized controlled trial (RCT). Contrary to expectation, scientific activity devoted to conducting RCTs and the synthesis of the findings of multiple RCTs (systematic reviews) have not ignored well-being and mental health as outcomes of importance and interest. A search for the term 'wellbeing' on the world leading Cochrane Collaboration Web site yielded 96 'hits' on well-being (http://www.cochrane.org/search/site/wellbeing accessed 18.12.13.) and 243 on 'well-being.' Frequently targeted population subgroups were cancer patients, women in labor, the fetus, older children, adults in stressful environments. Just to pick out a couple of specific examples: a completed systematic review of flexible working conditions and their effects on employee health and well-being (the findings of which 'seem to indicate that flexibility in working patterns, which gives the worker more choice or control is likely to have positive effects on health and well-being'); a protocol under development for a systematic review of organizational interventions for improving well-being and reducing work-related stress in teachers; a completed systematic review of parental training for improving parental psychosocial health.

Mental Health Promotion and Prevention

At the heart of initial thinking on mental health was the idea that mental health is a value and a state to be taken note of, considered and given attention to. This set of values was intended to be applied not just to those who are well (not mentally ill) but also to those with mental disorder including those suffering from its most severe forms. What began as a much needed set of values and principles has not, however, been taken up in the form of scientifically supported evidence development and testing leading to the effective prevention of mental disorders (see also Prevention Research).

Well-being and emotional health is central to the mental health promotion movement (see also Health Education and Health Promotion). Various activities have been suggested as increasing well-being and mental health including, activity and expressive therapies, meditation, biofeedback, counseling, and psychotherapy.

Selected, Indicated and Universal Prevention

If achieving mental health is substantially about prevention of mental disorder, progress with the latter deserves effort and attention. Gains have been made in two areas: providing resources to families and small children, and identifying adults at high risk of developing mental disorder and providing early intervention similar to psychological treatment. There is some evidence that parenting programs improve parental psychosocial health and child outcomes (Sandler et al., 2011; http://summaries.cochrane.org/CD002020/parent-training-for-improving-parental-psychosocial-health). One of the most promising long term, experimentally designed programs was designed to promote resilience of parentally bereaved children and their bereaved surviving parent (Sandler et al., 2010).

Evidence for the possibility of preventing mental disorders in older children and adults has come mainly from clinical researchers expanding the range of techniques that are effective treatments, such as cognitive behavior therapy (CBT), to a wider range of individuals than those who would normally be treated, such as those at high risk of developing, for example, depression, in the near future (Munoz et al., 2012). Thus there are now several studies showing that children in the final years before leaving school who already exhibit symptoms of depression (but are not clinically depressed) do benefit from CBT approaches applied within schools at a group level. Targeting older school children at high risk of becoming cases of depression with school-based psychological prevention programs seems to be effective (Garber et al., 2009).

Prevention and Policy

Quite appropriately, the global mental health movement has prioritized the narrowing of the gap between the burden of mental disorder and the delivery of care and services particularly in less-developed countries of the world (Prince et al., 2007). When mentioned, it is acknowledged that there is little evidence on which to base prevention but that governments should follow the evidence that exists. But how well would this work? One country has made the prevention of depression in adulthood a matter of national policy, the Netherlands. However, although indicated prevention of depression is available for about 80% of the Dutch population at little or no cost, only a small proportion of those with subthreshold depression make use of these services (Cuijpers et al., 2010). Most ambulatory mental health services have a prevention department serving the local or regional community but only 1% of adults with subthreshold depression access these services, which make use of a group-based depression prevention intervention, 'Coping with Depression' (Lewinsohn, 1987) that has been shown to be effective. While, it is important to find ways of persuading more people to consider using these approaches different ways of delivering prevention interventions are needed that overcome possible barriers including stigma, denial, and hopelessness (Cuijpers et al., 2010).

Selected and indicated approaches, for example, targeting high-risk groups face a further limitation: the relatively few who benefit are unlikely to alter significantly population prevalence and thus societal burden. This has lead to the recommendation to position prevention services in primary care or to integrate prevention interventions in community-wide interventions (Cuijpers et al., 2010). RCT-based evidence for prevention, particularly covering the whole population, offers the hope of measurable declines in the prevalence of depression attributable to prevention programs. But universal prevention trials are extremely rare in the

mental health field partly because they require the involvement of substantial numbers of participants and are therefore very costly (Munoz et al., 2012). Particular windows of opportunity do exist when people face challenging life transitions and have normal high contact with experienced health professionals, for example, during pregnancy and after childbirth. At such times there is both increased actual or perceived risk and normal access to nonstigmatizing care. Encouraging evidence that such a phased psychological service reorganization, possibly lowering the risk of depression, could be acceptable and feasible comes from a cluster RCT (Morrell et al., 2009). Women who scored positively on a postnatal test for depression were given guided psychological support based on counseling or cognitive behavioral principles provided by their community health visitor (who had undergone additional psychological training). In a secondary analysis of the same RCT (Brugha et al., 2011), postnatal women at 4–6 weeks following childbirth testing negative on the Edinburgh Depression Scale (Cox and Holden, 1994) were less likely to develop later postnatal depression if attended by a health visitor trained to offer the additional psychological support. Development of symptoms of depression was also experimentally shown to be less likely where the health visitor had also evaluated and discussed with the mother her risk of depression 6–8 weeks after childbirth. The same research group has since pilot demonstrated that services for women during pregnancy provided by community midwives can undertake the necessary additional training and follow the same model of treatment and prevention, but large-scale trials are needed to test this promising approach fully.

Primary Care Mental Health

As the previous section shows, primary care is a key setting for understanding and promoting mental health. The same epidemiological surveys mentioned earlier also show that most forms of mental disorder are mild in severity and adults suffering from them are often in contact with primary health care services, rarely engaging with specialized services. While the accent is on the medical model of disorder detection and treatment, primary care physicians increasingly view mental health as they do physical health as a responsibility attached to their role. A sign that not all is as it should be is consistent evidence that a significant proportion of prescribing of psychotropic medication is being taken up by the mentally well part of the population (Brugha et al., 2004; Kessler et al., 2005), which seemed to occur following a period of rapid expansion in prescribing particularly of SSRI antidepressive medication. It is not known if this is a sign that individuals are being prescribed in order to prevent recurrence of previous depressive disorder, or if it is a sign of unnecessary prescribing of preparations that are increasingly known to be effective only for moderate to severe forms of depression, or represents dependency. It may also reflect demand from service users who should be encouraged and supported instead to address possible causes in their lives and to pursue lifestyle activities that are thought to promote well-being, physical and mental health.

Conclusion

The achievement of mental health can be an outcome in its own right but cannot be completely separated from considering mental disorder and its prevention and early treatment. Mental well-being is a term that is increasingly occupying the space originally intended by the term 'mental health,' which often is used as a nonstigmatizing term for mental disorder and for psychiatry. Far too little research is devoted to prevention of mental disorders thereby, promoting mental health but there are seeds of promise that need to be nourished.

Mental Health and Social Work

Abstract

This article is about social work relating to people with mental health problems. It explores historically how the care and treatment of service users with mental health issues have developed. This exploration is informed by four key themes: the advances in psychiatric treatments, the ways in which mental health and recovery are understood, a changing landscape of policy and legislation, and the influence of those with lived experience of mental distress and those who care for them on the reform of the service delivery agenda. The article offers international examples to illustrate the above and considers the role of mental health social workers in respect of the dilemmas, challenges, and opportunities that arise from the work they do.

Introduction

The World Health Organization (WHO, 2001) defines mental health as a state of well-being in which an individual realizes their abilities, can cope with the normal stresses of everyday life, can work productively or fruitfully, and is able to make a contribution to his/her community (WHO, 2001: 1). In contrast, mental ill health includes mental health problems and strain, impaired functioning associated with distress, symptoms and diagnosable mental health disorders such as schizophrenia and depression. In terms of prevalence, the WHO (2000) reports over a third of people in most countries with symptoms meeting criteria for one or more common mental health problems. Not surprisingly then mental ill-health is a worldwide public health concern accounting for a significant proportion of the global burden of disease. It is influenced by individual and family, biological, social, ecological, and environmental factors (European Commission, 2005: 4).

Within this article a social work contribution is important because often associated with mental ill health are conditions of disadvantage, stigma and trauma reflecting the legacy of social work as a profession rooted in societies' struggles to deal with poverty and associated social crises. These beginnings in Western Europe and North America following the Industrial Revolution in the nineteenth century and continuing into the present day, for example, in South Asia in response to armed conflict and the tsunami of 2004 (Fernando and Weerackody, 2009).

In England, the history of mental health social work can be traced back to the 1800s when the wife of Alfred Meyer, a psychiatrist, visited her husband's patients to learn more about their home backgrounds; and was later called a 'social worker' (MIND – 29.04.2008).

Modern day mental health-related social work is practiced in some way and to some degree in the majority of countries and has seen some significant changes since its early beginnings in the last century. These changes have been influenced by advances in psychiatric treatments, the ways in which mental health and recovery are understood, a changing landscape of policy and legislation, and the influence of those with lived experience of mental distress and those who care for them on the reform of the service delivery agenda. It is to these four areas that this article now focuses in turn whilst recognizing that these areas are inextricably linked and exert mutual influence.

Advances in Psychiatric Treatments

While social workers are less concerned with diagnosing mental disorders compared with their medical and nursing colleagues it is important that they are able to assess how the signs and symptoms of distress may present and the treatment options that are likely to be made available to individuals. The legacy of medical treatments dates back to the Arabic empire between the tenth and thirteenth centuries with the first medical approach to madness pioneered in 'moristans,' which were a kind of forerunners to the asylums in Spain in the fifteenth century. Fernando (2010) explains how these European asylums evolved to be under religious jurisdiction, and were devoted to treating mental illnesses such as melancholia and conditions resembling obsessive-compulsive disorders.

Between the Middle Ages and the twentieth century, different conceptions of madness prevailed depending upon a society's belief systems and political persuasions, shifting from spiritual to physical explanations. Concomitantly care and treatment developed from the increasingly punitive and harsh regimes of the early madhouses and asylums to the more humane approach which saw asylums renamed as 'mental hospitals' and inmates as 'patients.' The asylum era of the early nineteenth century took off in Europe and colonial states with these mental hospitals paving the way for a greater reliance on the contribution of medical doctors to the treatment of the mentally disordered. By the late 1800s doctors openly recognized mental disorder as a form of illness, biological and pharmaceutical treatments dominated and the symptoms of schizophrenia were first described by Kraepelin in the 1890s.

Compared with England and Europe treatment for mental illness was less hospital-centered in the United States until the Second World War. With the increase in conditions that came to be termed 'shell shock' there was a greater realization of the contribution of social and environmental stressors to psychopathology which coincided with the development of social work and clinical psychology as professions. Lewis (1974) reported on the introduction of training for social workers in the US in the early part of the twentieth century.

Despite a global trend of deinstitutionalization and the upsurge in community care in the twentieth century many mental health professionals, service users, and their families would contend that the disease model characteristic of the institutional era continues to dominate treatment interventions even to the present day. Although from the early to mid-1900s, mental disorders were seen to arise from a more complex interplay between genetics, biological vulnerabilities, and stress a hierarchy of models for understanding mental distress prevailed with an associated hierarchy of treatment modalities (see **Figure 1** below). According to Bond and Lader (1996: 4) "The notion of an illness implies that there is a fundamental difference from normal, and a categorical rather than a dimensional approach is therefore preferred." Whilst the hierarchy of models suggests a more multidisciplinary approach to mental health care that came to the fore from the 1970s onward (see Bailey, 2012), social work interventions in the form of social and practical support and more psychosocial-oriented talking treatments were subsumed within an overall approach based on a premise that once the illness was medically treated the need for other forms of intervention would be negated as the signs and symptoms would improve. Historically such treatments have revolved around psychotropic medication and the use of electroconvulsive therapy (ECT) with psychological therapies playing a comparatively insignificant role.

This way of working, while acknowledging professional contributions other than medicine to interventions for mental ill health, has maintained the differential status of the other professions relative to psychiatry and set the scene for resistance to a more integrated interdisciplinary approach that has subsequently been deemed necessary to meet the diverse needs of service users in the twenty-first century.

Against this back-drop, mental health social workers need an understanding of the treatments for disorders spanning the neuroses (predominantly disorders of emotion with symptoms that are commonly recognized) to the more severe psychoses usually characterized by disorders of thought and/or perception. In some countries such as England, Australia, and the US, social workers may be called upon to assess whether such disorders are severe enough to pose a risk to the safety of individuals and/or others and as such warrant compulsory treatment in hospital although increasingly nowadays this can be enforced in the community.

Anxiety disorders may be generalized or specific like phobias and also include obsessive-compulsive disorder. They are usually treated using newer Selective Serotonin Reuptake Inhibitor drugs alongside talking treatments such as cognitive behavioral therapy (CBT). Posttraumatic stress disorder is typified by severe anxiety symptoms and flashbacks usually in response to some sort of significant life event, crisis or trauma. The relationship between childhood abuse and neglect and symptoms of mental ill health in adulthood (e.g., self-injury) is increasingly being seen as mediated through a type of post-traumatic stress response.

Mood disorders include those considered to stem from a reaction to a life event usually involving loss (e.g., symptoms of depression in response to bereavement) through to those where the cause seems elusive and is usually attributed to an internal biochemical imbalance. Severity varies from mild to major depression and bipolar disorder (also known as manic depression) is typified by abnormally high or pressured mood states often with associated thought disorder and problems with concentration/perception. Treatment varies depending upon an assessment of the individual's symptom profile and a range of interventions may be offered from antidepressant therapy with or without CBT, through to a combination of mood stabilizing drugs such as lithium preparations and carbamazepine augmented by antidepressants in small doses (Bond and Lader, 1996).

Treatment for psychotic disorders such as schizophrenia may also vary depending upon the extent to which symptoms such as hallucinations and delusions override those of withdrawal and lethargy (referred to as negative symptoms) which

Figure 1 Hierarchy of models of mental distress in the mid-1900s.

Figure 2 Recovery model of mental distress.

can look more similar to depression than psychosis. Treatment regimes have progressed from the major tranquilizers such as chlorpromazine to drugs such as clozapine which is now regarded as particularly effective for the treatment of these 'negative' type symptoms.

Increasingly, the importance of detecting the onset of psychoses early and using prevention techniques associated with the identification of prodromal symptoms has become the focus for modern day mental health care. Social workers in mental health are likely to find themselves helping service users and their caregivers to identify signs of deterioration in mental health before a full-blown psychotic episode develops. These 'relapse signatures' once identified can be especially important for individuals to learn how to manage their mental health more effectively (Nelson, 1997) and it is therefore important for social workers to be able to work with relapse signatures to prevent unnecessary hospitalization (Brown, 2009).

Diagnostic tools like the DSM-IV (in the US) and the ICD-10 in the UK are perhaps the most common but not the only classification systems that are used to help mental health professionals identify, through the process of an interview and assessment, the different types of mental disorders with which individuals may present.

Whilst the existence of such tools suggests that disorders fall neatly into specific categories this is often not the case. Eating disorders, for example, often present with associated symptoms of depression and anxiety and altered perception of body shape which can take on an almost delusional quality particularly in anorexia nervosa (Fernandez and Rothery, 2000). Personality disorders, characterized by abnormally rigid and maladaptive traits with associated behaviors that may be acutely dysfunctional or more chronic and difficult to manage also often present with symptoms of depression and overwhelming distress (Ladd and Churchill, 2012).

Where mental health social workers are particularly skilled as a result of their training and professional development is in recognizing the interplay of risk factors for mental ill health and in using individual and family-focused techniques such as CBT, systemic family therapy, and dialectical behavior therapy to intervene.

Mental Health and Recovery

The move toward more holistic frameworks for understanding why people's mental health deteriorates include the stress vulnerability model as mentioned above (Zubin and Spring, 1977), the biopsychosocial model (Engel, 1977, 1980), and the recovery model (Deegan, 1988; Anthony, 1993). The latter, in particular, reflects a recognition that modern day mental health practitioners increasingly need to adopt a 'being with' rather than 'doing to' approach when working with service users (Hinshelwood, 1998).

Interestingly, despite the advances in psychiatric treatments identified above long-term international studies of schizophrenia (Harrison et al., 2001; Jobe and Harrow, 2005) have found that medication makes little difference to symptoms in about a third of service users whilst another

third will report a reduction in symptomatology that may be accompanied by a regaining of social and psychological functioning, sometimes without any medication. According to Romme and Escher (1989) who have pioneered work on voice hearing in the Netherlands, neuroleptic medication has little effect on voices heard by individuals with a diagnosis of schizophrenia but do reduce the anxiety and distress often provoked by the voices.

Similarly, of people diagnosed with bipolar disorder, around half report a recovery from symptoms usually within a 6 week period with nearly all achieving this within 2 years (Tohen et al., 2003). Unfortunately, for service users with this type of disorder relapse tends to affect more than half with individuals.

What these studies suggest to mental health social workers is that there will be times when individuals with mental health problems are well and will be better able to develop coping strategies for managing their symptoms that manifest when they are ill. This in effect is the essence of the 'recovery model' which acknowledges that individuals may continue to experience symptoms of mental distress whilst retaining a high degree of control over their lives.

Seen as a process, rather than a state of being, effective 'recovery' draws from social, psychological, and medical explanation of mental health and illness, embracing these contributions from the different disciplinary groups to best effect and including the experiences of the person with the mental health problem and their family. This is perhaps most clearly articulated by Perkins and Repper (1998: 25) who assert that "different people adopt different models for understanding what has happened to them … organic constructions … psychological, social, religious or spiritual formulations. People have a right to define their own experiences for themselves and it is rarely helpful and more likely to be alienating-for the clinician to insist that their understanding is correct" (**Figure 2**).

The recovery model also allows for the influence of culture on understanding mental distress. For example, in African and Asian cultures individuals experiencing symptoms may be more likely to turn to traditional healers rather than access approaches that stem from mainstream Western psychiatry. The recovery approach also chimes with an increasing interest in the concept of well-being as a way of paying greater attention to how individuals attribute meaning to their mental health. According to Diener and Suh (2000), well-being is based upon the values and standards people ascribe to in their lives, their success or failure in achieving outcomes and pursuits which they personally seek and their ability to achieve fulfillment of their basic human needs.

Therefore, rather than assess how a service user's symptoms of mental ill health can be eradicated social workers need to be more concerned with what help and interventions can be mobilized to assist the service user manage their mental health needs. This stance supports risk management as a shared endeavor requiring more emotional closeness or 'hands on approach' (Ramon and Williams, 2005) with the social worker genuinely interested in the everyday concerns which matter most to the service user.

Bracken and Thomas (2004) identify this 'thinking outside' traditional models of mental ill health as 'post psychiatry' of the twenty-first century. They see approaches to recovery and well-being as inextricably linked with the concept of citizenship which they define as "being free from discrimination, exclusion and oppression" and "being able to define one's own identity and celebrate this in different ways" (Bracken and Thomas, 2004: 6). This is an important concept for mental health social workers to grasp as individuals often report that their experiences of discrimination and exclusion as a mental health service user are often more serious than the signs and symptoms of their mental distress that they cope with on a day to day basis. Social work interventions should, therefore, tailored toward countering discriminatory practice and promoting interventions that increase individuals' understanding of their mental health needs and how they might work collaboratively with mental health professionals to achieve positive outcomes.

Policy and Legislative Reform

In 2013, three-quarters of countries around the world have mental health legislation to prevent people with mental health problems being detained in hospital against their wishes. This trend of legislating for detention and the giving of treatment dates back in some countries to the early twentieth century. According to Unsworth (1987: 5), mental health law forms the foundations of the mental health care system which influences the 'intricate mechanisms of control, surveillance and discipline.'

For example, in England the 1930 Mental Treatment Act provided for voluntary treatment and psychiatric outpatient clinics. As mental disorder became increasingly medicalized as opposed to being seen as the manifestation of immoral or criminal conduct the Royal Commission on the Law Relating to Mental Illness and Mental Deficiency was set up and resulted in the Percy Report in 1957. The key themes of this report were that mental disorder should be regarded "in much the same way physical illness and disability" (para 5) and that mental hospitals should be run as nearly as possible like hospitals for physical disorders. This trend has been replicated in the way that mental hospital services evolved over the last century throughout the world.

The role of social workers in the assessment and treatment of individuals with mental health problems has been introduced at different times and in a range of ways in different countries. In 1913, three clinical social workers were introduced to the hospital in the United States and set the trend of clinical social work which today revolves around education, discharge planning and linking service users and their families to resources.

In England, it was the 1959 Mental Health Act that introduced the role of the Mental Welfare Office (MWO) as an applicant for the admission to hospital based on the recommendations of two medical practitioners. Eventually, MWOs were replaced by Approved Social Workers with the introduction of the 1983 Mental Health Act. In the UK, Approved Social Workers, and in the US, clinical social workers, require additional training and specialism in psychiatry in order to be able to fulfill their statutory responsibilities. In the US, clinical social workers are required to be licensed to practice in any state across the country, while in the UK, the registration of

Approved Social Workers has been undertaken at a local level by social services departments. Since the introduction of the 2007 Mental Health Act in England and Wales, other mental health professionals such as Community Psychiatric Nurses, Occupational Therapists, and Clinical Psychologists can take on the statutory role and remit historically limited to Approved Social Workers if suitably trained and experienced. The professional title has changed to an Approved Mental Health Professional to reflect that individuals fulfilling this role can now be drawn from a range of disciplinary backgrounds.

The conditions that relate to hospitalization or in some countries compulsory treatment in the community differ in the degree to which they require the presence of mental disorder, the need for treatment and or the assessment of risk in the form of a threat or danger to oneself or others. Salize (2006) identifies that in the existence of mental disorder *and* the existence of a threat or danger has to be present for involuntary admission in France or Germany whilst in England, Wales Portugal, and Finland the need for treatment must also be demonstrated. In Sweden and Italy, if mental disorder is evident alongside a need for treatment, this can be sufficient to warrant compulsory admission and the risks of threat or danger do not apply. Similarly, countries across the globe also differ in the ways in which they define mental disorder. Increasingly, the issue of mental capacity is defined separately and dealt with by related legislation to that which deals with mental illness. A significant change made by the Mental Health Act 2007 in England and Wales was that it introduced a singular definition of mental disorder as 'any disorder or disability of the mind' resulting in an abolition of the categories of mental illness, psychopathic disorder and mental impairment that were present in the 1983 Mental Health Act. The latter is now dealt with by the legislation relating to mental capacity.

This shift in the definition of mental disorder occurred alongside an extension of the definition of medical treatment in England and Wales to include: "nursing, psychological intervention and specialist mental health habilitation, rehabilitation and care" (Mental Health Act, 2007) which accords more closely with the recovery model of mental health outlined above (Bailey, 2012).

As well as setting out conditions under which individuals with mental health problems may be compulsorily treated mental health legislation also provides for a right of appeal either by the service user directly, indirectly by their caregivers or increasingly with the help and support of independent advocates. In this respect, mental health law begins to dovetail with the Human Rights Act of 1998 that incorporates the Convention for the Protection of Human Rights and Fundamental Freedoms usually referred to as the European Convention on Human Rights.

Article 5 of the European Convention on Human Rights deals with everyone's right to liberty and personal security and states that no one shall be deprived of their liberty except in certain circumstances and in accordance with a procedure set out in law. In Article 8, individuals have a right to respect for private and family life. The challenge for social workers in the field of mental health is to be able to make informed judgments, based on sound evidence where the individual rights of service users are superseded by the rights of the general public or other people who may be at risk from the service user's behavior, stemming from their mental health problem. This is never an easy decision-making process and one not to be undertaken lightly. Importantly, social workers need to be able to treat individuals with dignity and respect promoting choice wherever possible whilst recognizing that when people are unwell their choices may be limited. It is these fundamental values that inform best social work practice and which service users report are of most import to them.

Influence of People with Lived Experiences of Mental Ill Health and Those Who Care for Them on Service Development

According to Gosling (2010: 38), "Involvement is a two-way street – involvement is not just about us being involved in your (mental health professionals) lives – it is about you being involved in ours." In the UK, Gosling has been one of the key social activists in involving service users in the training of mental health social workers since the early 1980s.

The influence of individuals and their families on mental health care began once the programs of deinstitutionalization got under way in Western countries (Bailey, 2012). The survivor movement in the UK gathered momentum from the 1950s onward in response to individuals' experiences of psychiatric treatment. For example, a number of individuals began to report lasting memory impairments as a result of ECT and subsequently to speak out about the long-term consequences of their disability. What survivors of the psychiatric system seemed to have had in common was a collective experience of social oppression and discrimination being articulated more widely by the disabled peoples' movement in the UK as disability politics came more to the fore. Berresford and Wallcraft (1997), however, explain how the survivors' movement was in turn distinct, as a result of the mental health context. They also emphasized that the success of service user organizations such as Survivors Speak out in the UK was down to this being an organization that embraced people from a 'broad church' of backgrounds and political persuasions with no pressure to conform to a particular belief system.

Since the 1950s the number of service user groups has proliferated largely in response to policy changes such as the National Service Framework in England and similar policy initiatives in other countries (e.g., the National Mental Health Program in Norway). These developments have meant that the involvement of people with lived experiences and their families in the way that care and treatment is delivered is recognized and articulated as best practice at government level even though its implementation at a local level may remain fraught with complexities and a challenge to achieve.

The lobbying on behalf of those with mental health issues is increasingly undertaken on an international scale by a growing range of independent non-government organizations/charities. In 1946 the National Association of Mental Health in the UK joined other organizations to form MIND (a charity organization) in 1972. Basic Needs is an international mental health charity working in India, Ghana, and Vietnam since 1999, and SANE Australia (another charity organization) has

been in existence since 1986. These organizations undertake a range of functions on behalf of citizens and their families. These range from providing help lines and information to research into treatment interventions and campaigns to improve services and inform policy and legislative change. For example, MIND has recently responded to the current policy initiative of Improving Access to Psychological Therapies in the UK commenting that whilst greater access is welcomed waiting times in some areas are still problematic and regional variation of services is of increasing concern.

Other national service user groups and networks have played a key role in changing the way professionals think about and intervene with specific mental health issues. The National Hearing Voices network for example has redefined voice hearing as no-longer the debilitating condition associated primarily with schizophrenia that is was understood to be in the age of the asylum. Instead/with contributions from the likes of Romme and Escher in the Netherlands and Ron Coleman in the UK voice hearing has been demystified. Today it is understood as often a natural and short-term response to trauma or an experience which can be controlled and lived with using a range of cognitive and behavioral strategies. The premise of the hearing voices network is on the value of self help and peer support.

In the case of the latter, there is a growing body of literature testifying to its value for a range of other mental health conditions and influence on the creation of peer support roles in the mental health workforce, in America (Davidson et al., 1999), Canada (Canadian Foundation for Healthcare Improvement, 2010), and Australia (McKenzie, 2012). These roles can augment; in important ways the statutory role of mental health social workers as peer support workers can provide more hands on practical help to prevent crises and hospitalization. They can also provide valuable information about how service users and their caregivers are managing on a daily basis that in turn can assist mental health social workers make a judgment about whether compulsory treatment is necessary. For these reasons, peer support workers are becoming key members of multidisciplinary mental health teams such as Crisis Assessment and Treatment Teams in Australia and Assertive Outreach Teams in the UK.

Involvement in one's individual care package and more collectively with service user groups and organizations is reported to offer a wealth of benefits for service users such as a strong sense of self-worth and shared experience and understanding. In a systematic review by Crawford et al. (2002), 42 studies described the outcomes of involving service users and revealed that although some people were dissatisfied with the process of involvement, others welcomed the opportunity to participate, and their self-esteem improved as a result. In several of the 42 studies, staff also found the experience of involving those who used the service rewarding. Changes to services most frequently reported as a result of participation were the production of new or improved information for individuals about their care, alongside efforts to make services more accessible through improved appointment procedures, opening times or transport arrangements. In the same review Crawford et al. find examples of new services being commissioned at the request of service users. Other effects of involvement included more favorable staff attitudes and organizations becoming more 'open' to the concept of involvement.

However, Gosling (2010) would argue that 'involvement' is only a step toward service user emancipation that allows individuals to take power from the professionals rather than have it given. Stickley (2006) offers up projects such as the Service Users Research Group England (SURGE), User Focused Monitoring Schemes, and the Strategies for Living project at the Mental Health Foundation 2000 as examples of service users providing services to mainstream mental health services but not being managed by them. He argues that this places service user groups and organizations in a different position from which to negotiate collaboration and involvement.

The other group of individuals who have a role to play on influencing the development of mental health care and treatment are service users' caregivers. They can provide important information to mental health social workers to help in the decision-making process and have legal rights and responsibilities in relation to the care of their relatives. In England the National Service Framework (DH, 1999a) reemphasized the 'Care Programme Approach' (CPA) originally introduced in 1991, as the mechanism for care planning in mental health. The Framework stated explicitly how carers should be involved in the CPA (DH, 1999b) as a result of subsequent legislation (the Carers (Recognition and Services) Act 1995) which specifically outlines carers' entitlements generally not just in relation to mental health. In particular mental health social workers need to be especially concerned with the needs of young people caring for a relative with mental health issues as their rights are often enshrined in legislation that straddles that of adult mental health and child protection (Brown, 2009).

In some countries such as Scotland, Integrated Care Pathways have been developed (McQueen and Milloy, 2001) for service users and their caregivers as a guide to what each can expect to happen by certain stages of the assessment process. This kind of information can be especially troubling for young people who are often concerned what will happen to their relative if they talk openly about the types of mental health issues and risks they are dealing with.

Concluding Comments

The above account provides merely a flavor of the range and type of issues and opportunities facing social workers in mental health settings particularly given the complexity of the discipline and its international diversity. It remains for the author one of the most interesting and humbling areas of social work practice where the values of empathy, warmth and genuineness remain as fundamental. As the number of individuals with mental health issues grows globally the need for practitioners who can strike an effective balance between the preservation of human rights and the person-centered management of mental distress becomes ever more important. The landscape of mental health care in the twenty-first century requires that contribution from mental health social workers.

Mental Health, Mentalism and Sanism

Jennifer M Poole and Tania Jivraj, School of Social Work, Ryerson University, Toronto, ON, Canada

Abstract

Mentalism or sanism is a devastating form of oppression, often leading to negative stereotyping and arguments that individuals with mental health histories are not fit to study, work, or enjoy basic human rights. Despite 50 years of scholarship and recent developments in policy and research, the terms are still rarely used, understood, or interrogated in the social sciences. Indeed, social work in particular has been so loyal to the medical model that mentalist/sanist aggressions, such as pathologizing, labeling, exclusion, and dismissal have become a typical part of best professional practice and education. In this article, we provide an overview, history, analysis of, and response to mentalism and sanism.

Introduction

In this article, we detail mentalism and sanism with respect to mental health, locating our review in social work scholarship to date. We detail the roots of mentalism, their connection to the movements of ex-patients, consumers, survivors, consumer/survivors, and Mad people. We also explore the effects of sanist practices in particular on social work and suggest possibilities that not only respond to sanism but those grounded in critical, structural theoretical work, that support a practice of anti-sanism.

Tracing the Terms

Social sciences scholarship, and in particular social work literature, has long been known for its anti-oppressive analyses of issues such as racism, heterosexism, and ableism. Yet another form of oppression has received comparatively little attention – namely, mentalism as coined by the late American mental health consumer activist Judi Chamberlin.

In her foundational article on the ex- (mental health) patients' movement (1990), Chamberlin argues that in the early days of organizing, ex-patients (also known as consumers, survivors, consumer/survivors, users, refusers, lunatics, crazies, or Mad) identified mentalism and sane chauvinism as a set of negative assumptions which most people, including ex-patients themselves, held about 'mental patients.' More recently, mentalism has been defined as the systematic subjugation of people who have received mental health diagnoses or treatment. Like racism, mentalism may result in blatant discrimination, but will be most commonly expressed in "multiple, small insults and indignities" known as "microaggressions" (Kalinowski and Risser, 2005: p. 1). These microaggressions will include low expectations and professional judgements that such individuals are helpless, incompetent, violent, and irrational (Chamberlin, 1990).

In some circles, mentalism is also known as sanism (Birnbaum, 1960; Perlin, 1992). As explained by Ingram (2011), sanism was coined by Morton Birnbaum, a graduate of Columbia Law School who also gained an MD from New York Medical School. Influenced by the work and friendship of black legal scholar Florynce Kennedy, in 1958 Birnbaum began to argue for the constitutional right to adequate treatment for patients in US state mental hospitals. After it had been rejected by 50 other publications, Birnbaum's article, 'The Right to Treatment,' which outlined sanism, was published by the *American Bar Association Journal* in 1960. In 1980, Michael Perlin, a professor at New York Law School, applied Birnbaum's work, to identify discriminatory behaviors in law to which he had become accustomed and has focused his prolific scholarship on this issue ever since.

In the first of his influential papers, Perlin defines sanism as "… a form of bigotry that respectable people can express in public" (1992: p. 375). He notes how deeply the roots of sanism are entwined with social notions of sin, evil, God's punishment, crime, and demons (1992: p. 388). This linking allows for the labeling of "sickness as reassurance that the other … is not like us" (p. 390), creating the conditions in which those with mental 'illness' have been made largely invisible and without power, institutionalized, and deprived of the right to vote or the right to be parents (p. 392). It follows that certain sanist myths about people with mental health issues and labels have flourished. According to Perlin, these include the notion that such individuals are different, erratic, weak, frightening, and unable to make decisions or participate in the public arena. In addition, there are common myths that declining or refusing medications is a predictor of future 'dangerousness,' that mental health issues can easily be identified by lay persons, that what is depicted in the media is the truth, and finally that using pejorative labels to describe such people, including crazy, psycho, or insane is not as problematic as other recognized hateful terms. As inspired by Kimberlé Williams Crenshaw's work on intersectionality, like Birnbaum, Perlin recognizes that sanism cannot be disentangled from other oppressions.

Current Conceptualizations

Putting Perlin's work into practice, The Coalition Against Sanist Attitudes (CASA, 2011) explains that sanism and its myths about people with mental health issues have flourished because of particular factors. These include the practice of rejecting evidence to the contrary, basing our sanist responses on 'gut feelings,' anecdotes portrayed by the media, and our history of segregating and distancing ourselves (emotions, thoughts, behaviors) from those labeled as 'different,' odd, or psychiatrically 'unwell.'

 http://dx.doi.org/10.1016/B978-0-08-097086-8.28110-5

Another contributing factor is the dominance of the medical approach to mental health. The medical model is situated in a positivist or generally modernist paradigm. Born of enlightenment ideas which have subsequently privileged binaries, order, objectivity, de-contextualization, and the scientific approach to cure or recovery from illness, this paradigm has dominated western approaches to what is 'normal' or right with respect to social behavior, feelings, moods, actions, and desires. Anything outside this scientific norm is thus pathologized, categorized, and treated in accordance with medical/biological frameworks. With the best of intentions, this paradigm has seen the proliferation of conventional and (neuro)psychiatry, abnormal psychology, biological determinants of mental health, and binaries such as sane/insane and well/sick. All are centered on the individual as the site of the 'problem.'

In contrast, the theoretical roots of mentalism and sanism are aligned with a more structural, critical, or postconventional paradigm. Through these lenses, the focus changes to oppression, power, privilege, language, multiplicities of mood, emotion and ways of being, de-categorization, contextualization, connection, and the intersection of identity with multiple forms of oppression. In this theoretical place, we find mental health approaches that include but are not limited to feminism, antiracism and anticolonial work, critical race work, critical psychiatry, antipoverty work, anti-oppressive practice (AOP), social determinants of mental health approach, queer studies, narrative analysis, critical disability studies, sociology of the body, and, of course, Mad Studies.

Indeed, 21 years after Perlin's seminal piece on sanism, the conversation around mentalism and sanism has continued, especially in Mad Studies (see LeFrançois et al., 2013). For one such Mad scholar, mentalism speaks to the "mentalization or reduction of socially interpreted acts, feelings and thoughts to essential categories of mind, especially those not categorized as criminal" (Fabris, 2012: p. ix). Sanism is "the division of persons into 'mad' and 'sound,' especially based on an interpretation of ill logic, reason, or wisdom, such as in 'delusion'" (Fabris, 2012: p. ix). However, it is sanism (rather than mentalism) that appears to be more widely used within the Mad community (Diamond, 2012). It has also been broadened by Hamer (2011) to include 'state sanism' and 'institutional sanism.' Inspired by Michel Foucault, state sanism orders all citizens into normal and abnormal categories. Institutional sanism assumes that the abnormal are unpredictable and violent. Through psychiatry, medication is then justified in creating docile and compliant bodies of these abnormal subjects, thus lowering their 'threat' to society.

Stigma and Sanism

Despite this work on sanism, there has been far more interest in stigma, with various theoretical models, approaches, and levels carefully articulated by a wide range of researchers. Of note is Goffman's description of stigma as a deeply discrediting attribute (1963). Similarly, many have been influenced by the work of Link and Phelan (2001) who break the process of stigmatization down into labeling and stereotyping. Other authors have drawn our attention to the dangers of internalized stigma which makes individuals fearful of seeking help and support and the notion of public stigma when the general public agree with negative stereotypes (Corrigan and Shapiro, 2010). However, according to Holley et al. (2012), most of this kind of research focuses on the individual being stigmatized and not on the sanist power relations that make stigmatization possible in the first place.

For this reason, some argue for a research and practice focus on sanism rather than stigma. CASA (2011) explains that the focus must be on sanism because it is sanism which makes possible and gives rise to stigma. Similarly, Thornicroft (2006) and Sayce (1998) argue that a focus on stigma was always too limiting for not only does it perpetuate medical conceptions/language around mental health, but it minimizes the jagged reality of widespread rights abuse and oppression (or sanism) experienced by Mad individuals. Large and Ryan (2012) have argued the same with respect to the sanist belief in the dangerousness of Mad people. Finally, in a recent review of stigma and anti-oppressive social work practice, Holley et al. (2012) find the term stigma to be grossly inadequate. Citing Castro and Farmer's work on HIV (2005), they argue that "stigma is often the tip of the iceberg … and has frequently served as a means of giving short-shrift to powerful social inequalities … that are much harder to identify and conceptualize" (Holley et al., 2012: p. 54). Indeed, some argue that a singular focus on stigma whether in research, education, or the media is itself a sanist practice.

Sanism and Social Work

Given this, as well as the dominance of the medical model and widespread social investment in sanist myths, it follows that rare is the acknowledgment of mentalism or sanism in social work. With few exceptions (see Holley et al., 2012; LeFrancois, 2011a,b; Poole et al., 2012), it is often the case that in social work "offensive and injurious practices are integrated into everyday procedures to the point where we no longer recognize them as discrimination" (Kalinowski and Risser, 2005: p. 2).

For example, some have argued that social work needs to be protected from dangerous practices by social work students with mental health issues and indeed that acceptance to social work programs be delayed in these instances. Some feel that social work educators should not allow students with these issues to graduate at all, and in some jurisdictions, national debates continue around (un)suitability, mental health disability, and social work education. These debates make sense given that social work has long been loyal to the medical model of mental health, pushing other approaches to the periphery. However, it is not the only possible orientation for social work scholars interested in the study of sanism. Indeed, more productive have been the critical theoretical approaches known as anti-oppressive practice AOP (Dominelli, 2002), intersectionality (Crenshaw, 1989), and the social model of disability (Barnes, 1998).

AOP is the latest iteration of critical social work, an approach that includes but is not limited to feminist, structural, and antiracist social work. An AOP stance assumes that there are multiple forms of oppression, that oppression is tied to unequal power relations, and that critical reflection on these matters is paramount (Healy, 2005). In addition, with AOP the focus must be on creating spaces that promote service users'

empowerment and working in partnership with those users in practice, pedagogical, and research settings.

Also used by Perlin, the second approach is intersectionality (Crenshaw, 1989). Originated by critical race and legal theorist Kimberlé Williams Crenshaw while thinking through how gender and oppression interact in Black women's lives, she wrote

> Consider an analogy to traffic in an intersection, coming and going in all four directions. Discrimination, like traffic through an intersection, may flow in one direction, and it may flow in another…and sometimes, from all of them. Similarly, if a Black woman is harmed because she is in an intersection, her injury could result from sex discrimination or race discrimination […] But it is not always easy to reconstruct an accident: Sometimes the skid marks and the injuries simply indicate that they occurred simultaneously, frustrating efforts to determine which driver caused the harm.
>
> Crenshaw, 1989: p. 149

With respect to 'mental health,' it can be similarly impossible to see if the 'injuries' incurred by a Mad person result from sex or race discrimination, from poverty, and/or from sanism.

Finally, the social model of disability (Barnes, 1998) locates the difficulties that Mad people face not only in their issues, but also in pathologizing and sanist societies. Depending on social location, gender, race, class, and sexual orientation, these power relations make it possible for individuals acting 'differently' to be taken against their will to the hospital; for workers to be denied employment because of 'mental health' histories; or for Mad students to be excluded from social work programs.

Through all these lenses (and like Perlin), it is now possible to identify sanist behaviors to which social workers have become accustomed. For example, social work discourses on mental health have become rife with references to diagnosis, classification, and inappropriate behavior, and are heavily influenced by positivist, traditional forms of research that regularly exclude service users from the production of knowledge. In addition, many of these courses are organized around pathology, intervention, and working with clients to 'stay on their meds,' and many researchers approach madness from a clinical rather than a critical or antioppressive stance. Such practices have often led to a divisive 'us' and 'them' mentality in social work where 'we,' the rational, well, social work practitioners/educators decide on and distance ourselves from 'them,' the irrational, 'ill' users of 'mental health'/social work services. Indeed, Kalinowski and Risser (2005) detail that this splitting ensures a lower standard of service for users of mental health services, and it promotes the unjust attitude that any medication/residence/job/education that is substandard for social workers is fine for users. It has also resulted in what Buckles and colleagues (2008) call "an unwillingness to learn about or adopt terms such as consumer, survivor or Mad, a refusal to include professionals with psychiatric disabilities and finally, complacency with regard to advocacy and responsibility for public education" (p. 259).

Additionally, these lenses allow social work to see that "like other liberation struggles of oppressed people, the activism of former psychiatric patients has been frequently ignored and discredited" (Chamberlin, 1990: p. 1). Seldom do social workers learn that, since the late 1960s, people with mental health issues have been organizing and questioning medical treatments, rights abuses, and forced institutionalization (Rheaume, 2002), and that the struggle against sanist assumptions was seen as best accomplished in groups composed exclusively of people with lived experience (Chamberlin, 1990). Rare is the acknowledgment that many within the Mad Movement will not 'fix and fit' themselves. Additionally, seldom are social workers aware that consciousness raising has developed into the international Mad Pride movement, challenging conceptions of normal and 'well' while celebrating madness through writing, research, organizing as well as annual festivals, marches, lectures, and art shows around the world (see www.madprideto.com).

Responses to Sanism in Social Work

Some suggest that the next step in responding to sanism in social work is by involving the Mad community in social work education, practice, and research, especially in community-based and participatory ways. In one such foray (Poole et al., 2012; Reid and Poole, 2013), research participants identified a dearth of alternative or nonmedical course options on mental health in social work and ongoing institutional resistance to requested accommodations such as extended time to complete assignments. There were also multiple instances of how madness has been languaged in the classroom such as the indiscriminate use of the term 'crazy' and fears that self-identified Mad students may be a danger to the school and/or others.

To combat this kind of sanism, arguments have been made to shift the discourse swirling around mental health in social work from 'danger' to discrimination; from 'fears of a threat' to awareness of a benefit to the 'profession,' and from talk of physical and chemical restraints to one of rights and accessibility. Arguments have also been made to ground a social work response to sanism in rights work at the local, national, and international levels. If social work were to align with advocacy bodies such as the Ontario Human Rights Commission in Canada, social work would shift its focus to sanism, knowing that sanism continues to be deeply embedded in institutions including education. Social work would understand that an example of this may be the common practice of mandatory social work student placements on specific days and at specific times of the week-days that may conflict with the early morning affects of certain medications. Social work would also acknowledge that sanism takes place when policies, procedures, requirements, eligibility criteria, or qualifications may appear neutral but amount to discrimination such as the common practice of awarding scholarships only to students in full-time attendance, effectively excluding those Mad students who may only attend on a part-time basis.

Toward Antisanist Practice

At present, there is no established literature on anti-sanist practice. However, drawing on the aforementioned critical approaches as well as the scholarship on sanism, anti-racism, and anti-oppression, anti-sanism may be the way forward.

In social science education, such an anti-sanist approach may involve more support for critical mental health courses and those that detail the Mad Movement. It may include a shift toward offering alternatives to courses that privilege medicalized 'mental health' practices and heavy penalties for sanist language use in publishing, teaching, and policy. In social science research, an anti-sanist approach may focus not only on inclusion but direction by individuals with mental health histories. It may mean a shift away from stigma research and toward sanism scholarship and more support for Mad Studies as a developing field. It may also mean the examination of sanist myths held by research ethics boards concerned that Mad scholars are unfit to carry out their own inquiries.

Additionally, in practice, and specifically social work, anti-sanist practice may mean a dramatic reworking of how Mad people are supported. It may mean an acknowledgment of sanist myths at work in our own lives, how medicalization is sanist, and a refusal to separate or segregate madness from its intersection with race, gender, and sexuality. Anti-sanist practice may also mean that professionals are allowed to own their own madness without fear of retribution.

In summary, this short review of mentalism and sanism demonstrates that although the terms were coined decades ago, social workers and social scientists have been slow to take them up or apply them in their work, an exclusion which is itself sanist. However, dedicated scholarship by Perlin, members of the ex-patients, survivor and Mad Movements, as well as those seeking to go beyond stigma demonstrate that sanism in particular has more currency than ever before. With respect to social work, there is still much that is sanist in its education, practice, and research, and much promise exists in the possibility of antisanist practice.

Abstract

Mental illness rarely has a single cause. Most episodes of mental disorder are created by a combination of (1) genetic factors, (2) nongenetic constitutional factors that are largely formed through early life experiences, (3) later life experiences that may predispose the individual to mental illness (sometimes called vulnerability factors), and (4) recent life events that can trigger the timing of a mental illness. It is difficult, but not impossible, to determine the relevant proportions of each of these in an individual subject, and this is complicated by gene–environment interactions, which may also precipitate mental illness.

Mental illness, like most types of illness, is multifactorial in origin. It can be influenced by constitutional and genetic factors, early and recent environmental factors, and cultural and social elements. These are best described in chronological format, with those more distant described first and the most recent described last.

Early Causes

Genetic Influences

The advances made by genetics in the last twenty-five years of the twentieth century have been enormous, and are discussed elsewhere (see, e.g., Genetic Studies of Behavior: Methodology; Genetics of Complex Traits Through the Life Cycle; Mental Illness, Genetics of). It may appear that few of these advances have yet had much impact on the causation of mental illness, because there have been few dramatic advances comparable with that of the identification of the gene for Huntington's chorea in 1987 (Gilliam et al., 1987). However, there has been a steady growth in knowledge, best summarized as incremental mapping, which has helped to place the genetic contribution to a wide range of mental illness, in context.

The standard methods of studying the genetic component of causation of illness are the same in psychiatry as in other branches of medicine. The relative genetic risk of having, or developing, a particular mental disorder is determined by three research approaches: family, twin, and adoption studies. Family studies identify people with the disorder through questions (probands); the rates of disorder are identified in other family members and relatives, and are then compared with the rates in the general population. From these figures, it is possible to compute the numbers of people likely to develop the condition at some time in the future (the expectancy rate or morbid risk). A higher rate in immediate relatives compared with others and greater rates than the general population indicate a genetic contribution to the disorder.

However, environmental factors may also contribute to risk in family studies, and twin studies are better at distinguishing the genetic component. Monozygotic (MZ) and dizygotic (DZ) twin probands are compared with their co-twins for concordance rates (i.e., the rate of co-occurrence of the disorder in the other twin). If the ratio of the concordance rates for MZ twins (who are similar to clones as they have identical genes) and DZ twins is significantly greater than one, the disorder has a genetic component. Because there is often a bias in reporting disorder, it is preferable to derive probands and their co-twins from twin registers wherever possible (Puri and Tyrer, 1998).

Even with twin studies, the effect of environment cannot be completely separated since there is a tendency, fortunately exhibited less now than formerly, for MZ twins to be treated as though they were the same person and to identify psychologically with each other to a greater extent than DZ twins. Adoption studies overcome this effect, and when they are carried out with MZ twins, are seen to their best advantage. Other studies include adoptee approaches in which one or both of the biological parents have the disorder but the adoptive parents have not, so the rates of disorder in the adoptees can be compared with a control population, and adoptee family studies in which the adoptee is the proband and the rate of disorder determined in the biological and adoptive parents.

The results of these studies, in general, show that there is a strong genetic contribution to bipolar mood disorder and schizophrenia with MZ/DZ ratios of greater than three (Hauge et al., 1968; Gottesman and Shields, 1976), but this falls far short of that shown by a disorder such as Huntington's chorea. A more common finding is that illustrated by personality disorder, in which twin studies suggest that most personality traits are equally contributed to by genetic and environmental factors (Livesley et al., 1998) and several models have been postulated for the interaction between them (Kendler and Eaves, 1986). Now that the human genome has been identified, the techniques of molecular genetics are being used increasingly to identify specific genes associated with psychiatric disorder, but to date, only one clear disorder has been identified, fragile X syndrome, which affects males mainly and has clear locus on the X chromosome (Sutherland, 1979). However, a range of other disorders has been shown to be associated with chromosomal abnormalities, and approximately 40% of the causes of severe mental handicap (Down's syndrome, phenylketonuria, tuberous sclerosis, Hurler syndrome, Lesch–Nyhan syndrome, and Tay–Sachs disease) are known to be caused by identifiable chromosomal abnormalities that are potentially preventable by genetic counseling (Weatherall, 1991; *see* Mental Illness, Genetics of). Genetics is also helping greatly in the understanding of common mental illnesses. In the last 40 years, there has been a great tendency to split mental disorders into smaller and smaller groups but the

genetic evidence suggests that they could be lumped into much larger components, with bipolar disorder and schizophrenia, showing much more commonalities than differences (Craddock and Owen, 2005), and the same applying to anxiety and depression (Kendler et al., 1995).

Environmental Factors before and during Birth

The time immediately before, during, and shortly after birth is a very vulnerable one for the fetus or newborn infant. It is at these times that anoxia can lead to brain damage. The most obvious manifestation of this is the loss of brain cells leading to learning disability in adult life, and better obstetric care and supervision of babies with low birth weight reduces this risk (Illsley and Mitchell, 1984). There have also been a number of studies suggesting that the development of other mental illnesses, particularly schizophrenia and related disorders, is linked to obstetric difficulties (Geddes and Lawrie, 1995), but there is some doubt about the methodology of some of these studies. More careful matching of cases and controls in a larger sample, however, has failed to replicate these findings, apart from prolonged labor and emergency Caesarian section being more common in schizophrenic probands (Kendell et al., 2000), and there is also increasing evidence that neurodevelopmental processes in intellectual disability and schizophrenia are related (Owen, 2012).

There is also evidence that infectious diseases, particularly when contracted before birth, may be associated with mental disorder. Schizophrenia is more common in those born in the winter months (Hare et al., 1973) and the case has been made, not altogether satisfactorily, that this could be a consequence of maternal influenza in the winter months (Adams et al., 1993). Another infectious disease linked to mental illness is rubella, which is associated strongly with learning disability (due to microcephaly), if infection is contracted in the first trimester of pregnancy.

Early Years of Development

The hypothesis that mental illness is a consequence of problems in early development has been active for many years and is one of the fundamental components of psychoanalysis. This argues that psychological conflicts encountered in early development that remain unresolved are likely to surface later in life in distorted form that psychoanalysis can succeed in decoding. This is perhaps best encapsulated in the phrase 'give us a child to the age of five and let who will have him thereafter.' Another approach initiated by the work of John Bowlby is the possibility that the earliest stages of the infant's relationship with its mother can also lead to problems that arise again in adult life. This has led to the growth of attachment theory (Bowlby, 1988) and has also stimulated psychoanalytical approaches to treatment.

These difficulties are often not associated with overt psychological trauma, or, if they are, it is usually within the bounds of everyday experience. More severe trauma is associated with a different range of pathology. There are now many conditions that have been shown to be associated with severe psychological trauma in the early years of life, including borderline personality disorder, post-traumatic stress disorder, recurrent depressive episodes, a range of problems of sexual dysfunction, and also, in recent years, a strong link between early trauma and psychosis, including schizophrenia, in adult life (Read et al., 2005). Depressive illness in adult life is also more likely to occur in those who have suffered the loss of a parent through separation, divorce, or death (Harris et al., 1986). This is postulated to be due to increased vulnerability to adversity after adverse early experiences. The long gap between initial loss and the onset of depression has been studied by life events researchers, and the concept of 'brought forward time' has been introduced to compare it with the immediate response to a major life event.

Late Causes

Later Environmental Causes

There are a host of environmental causes of mental illness from late adolescence onward that, unlike the previous ones described earlier, are determined to a much greater extent by the individual concerned. The group of conditions showing this characteristic most prominently, are the substance misuse disorders, as absence of indulgence can never lead to disorder. Although there are likely to be genetic factors that influence the extent that people become addicted to a substance (Kendler et al., 1995), by far the most important factor is repeated exposure, and this is primarily an environmental issue. Alcohol is the most important of the substance misuse disorders, accounting for one-third of all mental disorders and having harmful effects on around 10% of the population per year (Kessler et al., 1994), a staggering figure however it is interpreted.

Important gene–environment interactions have been noted for depression, where those with the shorter allele of the serotonin transporter gene have been noted to be prone to depression in the context of adverse events (Caspi et al., 2003), and for antisocial behavior, with those having low activity for the monoamine oxidase A gene being more prone to antisocial behavior after abuse than those with greater gene expression (Fergusson et al., 2011).

Other important environmental causes are infections. These include viral, protozoal, and bacterial organisms, and most recently, prion infections, such as the human form of bovine spongiform encephalopathy, and result in mental disorder when they affect the brain. The acquired immune deficiency syndrome, neurosyphilis, and viral encephalitis are the most important. Trauma to the brain is also an important cause of personality change and functional handicap, including dementia. Whenever the oxygen supply to the brain is significantly impaired, there is the danger of neuronal death and consequent organic mental illness, primarily dementia. Similar problems can be created by metabolic disturbances but these are more likely to be reversible. Thus a range of medical illnesses: hypertension, atherosclerosis, renal failure, hepatic failure, thyrotoxicosis, myxedema, sarcoidoisis, autoimmune diseases, and Cushing's disease (or any medical illness treated with steroids) may all be associated with mental disorder, of which anxiety, depression, and dementia are the most common.

A more common environmental factor influencing the onset and nature of many common mental disorders is social deprivation. Epidemiological studies have consistently shown that almost all mental illnesses are more common in the people of lower than higher social classes (Hollingshead and Redlich, 1958; Kessler et al., 1994). The reasons for this are much more difficult to unravel, but include specific aspects of deprivation (poorer material circumstances – greater crime, traffic pollution, substandard housing, unemployment), less control over direction in life, and a higher rate of adverse life events (Boulton, 1998).

Recent Stress as a Precipitant of Mental Disorder

The notion that stress is the cause of much mental (and physical) disorder is a very old one. It has been researched heavily in recent years by those interested in the effect of life events on mental illness. Although some of the early causes of mental illness might be perceived as stressors that create mental illness, the general notion of stress as a recent precipitant is rather a distant one. Early experiences may create a vulnerability to mental illness that is then activated by a stressful experience. These are often combined in the stress–diathesis model of mental illness that places mental illness and stress on separate scales: low stress being associated with no mental illness, greater levels of stress creating illness in those who have a vulnerable diathesis, and very severe stress creating symptoms of mental illness in almost anybody.

There are three specific mental illnesses that are defined as stress related: acute stress disorders, adjustment reactions, and post-traumatic stress disorder. All of these present primarily with symptoms within the neurotic spectrum (e.g., anxiety, panic, depression, irritability, social withdrawal), and satisfy the common definition that they would not have occurred in the absence of a psychosocial stressor. Acute stress disorders can occur in almost anybody when under intolerable pressures (e.g., car accident) but resolve rapidly when the natural processes of restitution take place (usually within 24 h). Adjustment disorders are longer-lasting, either because the stress is persistent (e.g., stress in a relationship) or because it is more intense. Post-traumatic stress disorder is associated with stress that is beyond the range of normal experience (e.g., earthquake, observing homicide) and is associated with specific symptoms, including flashbacks of the traumatic event, nightmares, extreme avoidance of situations that evoke memories of the event as well as the range of symptoms shown in adjustment disorders with generally greater intensity (particularly depressive symptoms).

However, although these conditions are defined by the nature of the stressful experiences preceding them, there are many others in which stress is a provoking factor. These are specific codes for stressful events in both the *DSM* and *ICD* classifications (American Psychiatric Association, 2013; World Health Organization, 1992) and in a full diagnostic summary, the nature of any associated stresses should be noted. In research work, stresses are often quantified into life events, whose intensity depends both on their nature and the extent of their (contextual) threat (Brown and Harris, 1978) and there have been numerous studies that show that the onset of almost all mental illnesses is accompanied by a greater rate of life events than those without such illness. It is difficult to know to what extent, however, these could be regarded as causes of the illness in the true etiological sense, and it is more common to regard them as triggers or provoking factors. Thus, for example, it has been shown that exposure to high levels of critical expressed emotion in patients with schizophrenia is more likely to provoke relapse than if more normal expression of emotion is shown (Vaughn and Leff, 1976) and interventions to reduce such emotion in families may have a beneficial effect (Pharoah et al., 2000). Even with this evidence, it is not suggested that critical expressed emotion is the cause of schizophrenia; it is the specific combination of a specific type of stress and its relationship to a particular illness that makes its effects shown. This 'Achilles' heel' phenomenon, the activation of an illness by a particular combination of circumstances, is very common in mental illness, and gives support to the stress–diathesis model for many of the most common conditions encountered, particularly those in primary care.

The multifactorial nature of causation of mental illness is illustrated in the following case report, based on a real patient but with some important elements distorted to prevent identification.

Mrs A came as a refugee from a country in sub-Saharan Africa where three members of her family were killed in front of her by rebels involved in fighting a civil war. She had become withdrawn and depressed after this, but was persuaded to flee the country by relatives and came to another country (the UK), where at the time she was being seen clinically, her application to stay in the country was being considered. Her relatives were also concerned that at times she had become more seriously disturbed and believed that her mind had been taken over by alien beings that had entered her body after a native witch doctor in her country had cursed her.

On assessment, she was shy but cooperative and keen to please. Her family history revealed that her mother had been unwell after one of her children was born and believed her body had been possessed by spirits that were preventing her from looking after her baby. A niece had also killed herself by walking into a swamp when unwell and allegedly possessed. During her childhood, she did well at school but had times when she lost confidence in her own abilities and had always been more anxious than her brothers and sisters. In general, she had always had low self-esteem. Mental state examination revealed that she was persistently anxious with episodes of panic, particularly at night and when her husband was away from home (he worked variable hours). She also had vivid nightmares of her parents being killed in front of her by men wielding machetes, and was unable to have any sharp knives in her kitchen because they aroused such high levels of anxiety. She also had periods of quite deep depression when she felt that life was such a struggle that it would be easier to take her own life than continue to fight. Direct questioning about her alien experiences revealed she still believed that she had been cursed, as indeed had her whole family, and that twitching movements of her hands and arms indicated that she was still under external control. She was also very anxious that her application to remain in the country as a refugee might not be granted and kept asking the services to intervene on her behalf so she could stay.

A diagnosis of post-traumatic stress disorder, comorbid generalized anxiety disorder, and recurrent depressive episode was made, and an unspecified diagnosis in the schizophrenia group, probably persistent delusional disorder, was also made.

Considering the causes of this complex problem, which is representative of many others who present to psychiatric services, the following etiological factors were considered:

1. the family history of possession and being cursed, which could have a cultural explanation, but which might be better explained by a family history of schizophrenia, which Mrs A would be then more likely to have, because of its genetic component,
2. the extreme stress occasioned by seeing members of her family killed in front of her (one of the characteristic features of post-traumatic stress disorder),
3. her lifelong tendency of low self-esteem and tendency to be anxious, and
4. her current anxiety about the real possibility of being asked to leave the country if she did not achieve refugee status.

The etiology of these problems can be described in the form of a tree, in which the main trunk indicates her fundamental diatheses, her possible tendency to develop schizophrenia, and the likelihood that she has some of the features of personality disturbance in the anxious/fearful group (cluster C) (a mixture of genetic and constitutional factors). The branches include the relatively recent experiences of seeing her family killed, and the most recent, more characteristic of an adjustment disorder, and indicate the stress of waiting to hear whether she would be allowed to stay in the country.

In constructing this tree, we need to be aware that there is a natural tendency for people to attempt to find causal explanations for everything in life, and sometimes these may be quite wrong. However, most of them have face validity, because in the search to make sense of a chaotic world, success in finding explanations makes it more bearable and also easier to recall – a phenomenon nicely described as 'effort after meaning' by one of the earlier researchers on the subject (Bartlett, 1932). Sometimes it is more accurate to say that the cause of a particular mental illness is unknown (idiopathic) but it makes us more authoritative to pick on a trunk, branch, or leaf of the etiology tree and give a suitable explanation.

Summary

The perceptive reader will recognize from reading this article that there is a great deal of more ignorance than knowledge when it comes to summarizing the causes of mental illness. A major deficiency in our knowledge is the ability to detect specific mental illnesses in advance of their manifestation. A great deal of energy is currently going into those who have what is called 'at risk mental states' or prepsychotic conditions that are likely to progress to full expression without intervention. At present, we remain remarkably poor at predicting which of these will progress to psychosis if untreated, and those that will resolve spontaneously. Statistical evidence of risk is of very little use to the average clinician unless it is at a high level (i.e., over 50%) and we rarely get this degree of prediction in psychiatry.

Abstract

Common mental disorders are seen to run in families. However the relative contribution of genetics and the environment is uncertain. While rare forms of learning disability, autism, and Alzheimer's dementia have been found to have single-gene causes, the vast majority of cases of common mental disorders, such as schizophrenia and bipolar disorder, exhibit a highly polygenic, complex genetic etiology with gene–environment interaction the rule rather than the exception. New genetic technologies and the completion of the human genome project have led to an explosion of new molecular genetic data; however, the relatively small contribution of each variant to relative risk for common mental disorders has meant that progress in identifying specific associated genetic variants has been slow. It appears highly likely that we all carry a degree of liability to develop common mental disorders, and that this liability is mostly explained by a large repertoire of evolutionarily stable common genetic variants. This concept of a broad liability throughout the population both humanizes these previously stigmatized conditions and also explains why the population prevalence of these disorders remains constant over time, despite the reduced fecundity conferred.

All common mental disorders (affective, psychotic, and anxiety disorders and addiction) aggregate in families due to genetic influence. The clinical phenotypes are heterogeneous without distinct boundaries. For each common mental disorder genome-wide association studies propose the involvement of multiple genes in addition to environmental factors. Modern molecular genetic techniques greatly facilitate the search for these susceptibility genes, although distinguishing contributory genomic variation from the statistical 'noise' of multiple association testing has proven challenging, requiring very large sample sizes.

Psychotic and affective disturbances were first described in the philosophical literature of ancient Greece under the concepts of mania and melancholia, which were considered as extremes of personality traits. In this epoch the familial inheritance of these disturbances had already been noted. This wisdom continued until the beginning of the nineteenth century, when these disturbances were first considered as medical diseases. During this century the new concept of degeneration stressed the accumulating effects of familial inheritance across generations and was applied to psychotic and emotional disorders. At the end of the nineteenth century alcoholism was additionally recognized as a major source of degeneration. Although the classical concepts of inheritance and degeneration did not specify the mechanisms of transgenerational transmission, both concepts prepared the basis for the eugenics movement starting in Anglo-Saxon countries. This ideology proposed methods of reproductive planning for increasing the health and welfare of humankind and for reducing the impact of diseases, criminality, and bad habits.

Twentieth Century Developments

Gregor Mendel was the first to postulate specific mechanisms of genetic transmission in plants. He was fortunate that he was working on traits that happened to be due to monogenic variation (that is, one mutation causing one variable trait). The relevance of this work was not immediately recognized. The rediscovery of the Mendelian law and the invention of the concept of genes in 1900 led to rapidly growing interest in the genetic hypothesis and its application to humans. Remarkably, the original concept of genes coding for physical and psychological properties was hypothetical and was developed without any knowledge of the physical existence or structure of genes (which became apparent only several decades later through the work of Watson and Crick). The early concept of genes already included the possibility that a gene could have multiple variants (mutations) with different functional consequences (polymorphism). Thus, the distinction between genetic and nongenetic influences became feasible. The familial transmission of patterns and disturbances of human behavior was also explored from a genetic perspective. The advantage of this was the development of systematic family and twin studies and their application to mental disorders, mainly in the 'Munich School' headed by E. Rüdin at the beginning of the twentieth century. Familial aggregation and genetic determination of most mental disorders was concluded.

These results were misinterpreted in the predominant 'one disease/one gene' perspective (monogenetic concept). This concept is valid mainly for rare genetic diseases, but not for common mental disorders. The eugenics movement in many countries was influenced by this misinterpretation, and served as the conceptual basis of programs to prohibit people affected from having children. Nazi Germany in particular established forced sterilization programs among patients with schizophrenia and affective disorders. This development is particularly surprising because it was noticed that many inherited behavioral traits did not conform to a Mendelian model of familial transmission. An etiology proposing many contributory genes (polygenic) to explain familial aggregation without Mendelian patterns of transmission was initially proposed in a paper by the British statistician Sir Ronald Fisher in 1918 (Fisher, 1918). However leading psychiatric geneticists

(e.g., E. Rüdin in Germany) appeared to be ignorant of these insights and continued to promulgate the monogenic, Mendelian origin of schizophrenia and manic-depressive illness. From the perspective of a polygenic etiology, the rationale of the eugenic movement becomes largely invalid, as prevention of affected groups from reproducing is unlikely to change the frequency of contributory genetic variants in the population.

Despite excellent empirical work, the genetic origin of mental disorders hypothesis did not receive much attention between the 1940s and 1970s. Several factors explain this lack of interest: first, the genetic hypothesis was seriously discredited by the morally disreputable eugenics movement focusing on these diseases; second, psychoanalytic thinking predominated in these decades in many countries (especially in the USA, until about 1970); third, the research tools for studying genetically influenced disorders without a Mendelian mode of transmission were very limited before the molecular-genetics era; and finally, tools for understanding complex interactions of genetic and environmental influences were more or less nonexistent in these times. Given this lack of genetic research potential the environmental causes of mental disorders were probably overemphasised.

Motivated by the emergence of biological psychiatry during the 1970s, family-genetic approaches to the etiology of mental disorders received growing attention. Family, twin, and adoption studies using newly developed epidemiological and biostatistical techniques were performed, exploring the etiology of, and the relationship between, different mental disorders. Particularly, the landmark Danish adoption studies by Kety and Goodwin changed the predominant assumption of the psychosocial origin of psychoses and alcoholism and motivated a nature versus nurture discussion that dominated the field for a decade. A refined arsenal of genetic–epidemiological methods was used to demonstrate the interaction between environmental and genetic factors as the etiological basis of common mental disorders. Gene–environment interactions appeared to be the rule rather than the exception. The results strongly argued against the oversimplification of the nature versus nurture debate.

Based on the discovery of the biochemical structure of chromosomes as long strings of DNA, and the process of gene expression as the production of functionally relevant proteins, the polymorphic nature of genes and the functional consequences thereof became apparent in the middle of the twentieth century. Genetic variability was found to occur as different variants of the gene itself (termed an allele), which might result in different gene products (proteins), or as variation in the promoter regions of genes, which influenced the degree of gene expression and consequently the quantity of the protein product. Within this framework, genetic causes of diseases could be identified at the level of DNA and also the protein product. Genetics thus became a basic tool for unraveling the pathophysiology of diseases and for the understanding and development of effective treatments.

The rapidly developing field of molecular genetics shifted the focus from the nature–nurture debate to the search for the genetic origin of diseases at the level of DNA variation. Stimulated by progress in unraveling the causes of monogenic diseases, extensive efforts are now underway to identify genetic variants of etiological relevance.

In the meantime, the genetic causes of most monogenic diseases have been detected, especially those characterized by severe or global impairment of cognitive function. Causal genes for rare forms of early-onset dementia of Alzheimer type have also been identified. These discoveries, however, appear to represent the 'low-hanging fruit.' More common mental disorders, such as schizophrenia and bipolar affective disorder, are increasingly seen as highly polygenic disorders where a spectrum of preexisting genetic liability to disorder exists in a complex interaction with environment (Uher, 2009). The completion and refinement of the human genome project and the subsequent HapMap project to identify and make available a database of human genomic variation has presented a unique opportunity to resolve the relative contribution of different types of genetic variation to common mental disorders.

The development of DNA microarrays, which represent a miniaturization of the Southern blotting technique developed in 1975, has been a particularly important contribution to the exponential expansion of new molecular genetic data seen in the early part of the twenty-first century. DNA microarrays allow the interrogation of the genome at thousands, or even millions, of known genomic locations on a single glass microscope slide. This has allowed massively parallel genomic association studies to be carried out on large numbers of samples at a cost effective rate. Microarrays using single nucleotide polymorphism (SNP) markers capitalize on the fact that SNPs represent unique genomic markers of known position within the reference human genome sequence that have only two possible forms (known as 'alleles') which, in a normal chromosome comprised of two chromatids, results in three possible variants – often arbitrarily denoted as 'AA,' 'AB,' and 'BB.' On a DNA microarray, each allele is tagged with a different flurophore that fluoresces a different color (usually red or green) depending on the genetic variation present within the sample being analyzed. In addition to these variant-specific microarrays, whole-genome sequencing arrays have been developed that allow the vast majority of the genome to be sequenced, base-by-base. Given the recent development of still other arrays that are able to interrogate epigenetic variation such as DNA methylation and microRNAs, the amount of genetic data is expanding at an exponential rate. The problem now arising is how this vast quantity of biological data can be meaningfully analyzed in common mental disorders and what benefits, if any, can be conferred at the clinical level.

The problem of multiple association testing presents a particularly thorny problem if, as is now expected, most of the genetic explanation for liability to common mental disorders arises from many genetic variants each contributing only a small increase in relative risk. Distinguishing true causal variants from the statistical 'noise' generated by multiple association tests may require sample sizes in the region of hundreds of thousands, or even millions, of samples. Rare variation may contribute substantially to risk in a small minority of cases, while a collection of common variants contribute toward risk in other cases, with still more cases having a contribution from both forms of variation. The picture in the majority of cases, it appears, will be very complicated.

Among the common mental disorders, schizophrenia and the affective disorders have been most intensively studied. The genetics of rare mental disorders, particularly early-onset

Alzheimer's disease and specific subtypes of mental retardation, have been extensively and very successfully studied; given the limitations of space these rare disorders are not included in this overview. The evidence related to epigenetic data, which will focus on analyses restricted to the DNA sequence itself, is still in its infancy at the time of writing and is also not covered in this review.

Specific Disorders

Schizophrenia

Among the common mental disorders, as mentioned in the preceding section, schizophrenia and the related psychoses have been most intensively studied from a genetic perspective. Schizophrenia is a disabling, lifelong disorder that can manifest at any age (lifetime prevalence 0.5–1%) but which is most often seen to develop in the second and third decades of life. The cardinal symptom is lack of insight, although delusions, hallucinations, thought disorder, and an amotivational or dysexecutive syndrome that results in disabling psychosocial decline and dysfunction (often called the 'negative' or 'deficit' syndrome) are also common. Schizophrenia is a very heterogeneous disorder, with no one symptom or sign being seen in all cases. Retrospectively it is often possible to identify subtle developmental problems in childhood, although these by no means predict the onset of the disorder. An extensive body of evidence suggests that schizophrenia represents a broad range of neurocognitive problems, which are themselves the result of subtle neurodevelopmental abnormalities resulting from a complex interaction between a polygenic liability to disease and precipitating and perpetuating environmental factors.

The familial basis of schizophrenia was first established early in the twentieth century. The risk to siblings of affected probands (proband being defined as the primary affected case in a family, or pedigree) is about 5–7%, resulting in a relative risk (lifetime risk in the group of interest divided by lifetime risk in the general population) of about 10. The risk among parents of probands with schizophrenia is reduced (3–5%) because schizophrenia confers a reduced fecundity (i.e., affected subjects have fewer children than random subjects in the general population). Currently, having a first-degree relative with schizophrenia shows the highest predictive power among all known risk factors for schizophrenia (*see* Schizophrenia).

Twin Studies

Twin studies explore the genetic impact on disease by utilizing the fact that monozygotic twins share 100% of their genes, while dizygotic twins share only 50%. By comparing the concordance rate among monozygotic and dizygotic twins, an estimate of the relative contribution of genes and environment can be made. A higher concordance rate for schizophrenia is consistently found in monozygotic compared to dizygotic twins (50% vs 10%). Estimates vary; however, this suggests a substantial genetic component (or heritability) of between 60 and 80%, but it also argues for the impact of non-genetic environmental factors (because if the disorder was entirely genetic in origin, the concordance rate between monozygotic twins would be 100%). By combining twin data with population prevalence rates, it is possible to distinguish three sources of etiological variance – genetic, non-genetic familial environment, and non-genetic individual-specific environment. There have been different conclusions from twin compared to adoption studies with regard to the relevance of familial environment for the emergence of schizophrenia; while this problem is unresolved, the relevance of strong genetic influences is unquestionable. Similarly, it is unquestionable that the inheritance patterns seen in schizophrenia are not Mendelian, but rather complex and reflective of a broad polygenic contribution.

Schizophrenia shares a series of features with other complex disorders:

1. Environmental factors operate in concert with genetic factors (evidenced by less than 100% concordance among monozygotic twins).
2. Penetrance of the phenotype is incomplete: the offspring of an unaffected identical twin of a proband (discordant monozygotic twins) have the same risk (10%) of transmitting the disorder to their children as monozygotic twins where both are affected.
3. The boundaries of the transmitted familial phenotype of schizophrenia are not distinct. Related syndromes and isolated symptoms are aggregative. That is, among the relatives of probands, characteristics of schizophrenia (that do not amount to a diagnosis) occur more often than expected by chance (e.g., attention deficit, abnormal patterns of neural evoked potentials, memory problems, and disturbances in pursuit eye movement) (Tsuang, 2000).

Molecular Genetics

The combination of the strong support for a genetic influence on schizophrenia from twin studies, the completion of the human genome project, and the ongoing cataloging of human genetic variation via the HapMap project, along with rapid advances in miniaturization of molecular genetic techniques, has resulted in a huge drive to discover the genetic basis of liability to the disorder.

Prior to the completion of the human genome project, the genetic linkage technique was used to probe the genome for regions linked to schizophrenia. This technique, enormously successful in identifying genomic regions associated with monogenic diseases was generally unsuccessful in schizophrenia (and many other complex disorders) largely because it can only detect variants of moderate or large effect. To this extent, however, a few families with highly transmissible (and very rare) forms of schizophrenia were identified, most notably a family in Scotland with a translocation between chromosomes 1 and 11, disrupting a gene that went on to be called *DISC1* (disrupted in schizophrenia 1), and now known to be involved with the regulation of neuronal axon and dendrite outgrowth. It is prescient and pertinent to note in this study that the clinical picture seen in affected individuals included psychiatric diagnoses other than schizophrenia.

The enthusiasm for genetic linkage at the time was largely misplaced, and represented not only the views of those who still believed that schizophrenia was caused by one or a few genes, but also because no other better technique for probing the genome in multiple locations existed at the time.

To this extent it was the development of the genomic microarray that revolutionized complex disease genetics in the early part of the twenty-first century. The microarray allows interrogation of the genome at vast numbers of unique genomic locations on a single glass slide and is far better suited to detect variants that may be contributing a relatively small amount of risk. The microarray is responsible for the initial explosion of new genetic data in complex disorders and the birth of the genome wide association study (GWAS). However with these new studies and new data came a difficult statistical problem – how to distinguish between a true variant of small effect and a variant that does not contribute to risk but is seen to be associated with disorder by chance because of the number of association tests being carried out (a statistical 'type 1 error'). The natural solution to such a problem is to set a statistical significance level that takes account of chance association in the thousands, or millions, of statistical tests being undertaken (widely cited in GWAS as the probability of a type 1 error of less than 5×10^{-8}). However in early GWAS studies, which did not utilize high sample numbers, this probably resulted in variants of small effect being lost within the statistical 'noise' generated by multiple association testing (a statistical 'type 2 error'). This is a problem of lack of statistical power, or the ability to detect an effect if one exists. The most obvious solution is to increase the number of case and control samples, however the mathematics involved revealed that the sample sizes of the early GWAS were insufficient to the extent of one, two, or even three orders of magnitude to detect an effect. This led to an all-to-familiar story of excitement over initial findings being quelled with disappointment over non-replication. This has led to an intensive global collaboration to combine sample sets and achieve adequate statistical power to detect variants with modest effects on relative risk, most notably resulting in the formation of the Psychiatric GWAS Consortium.

The largest and most technically proficient GWAS performed so far supports the theory of a polygenic contribution to liability for schizophrenia (Ripke et al., 2013). It is important to note that there still exists considerable variation between studies, and replication rates have, on the whole, been poor. The picture is in constant flux. In the Ripke et al. (2013) study cited above, eight replicated single nucleotide polymorphisms (SNPs) were associated with schizophrenia. Using approximate Bayesian polygenic analysis, the authors estimate that there are 8300 SNPs across the genome that contribute risk for schizophrenia, accounting for 50% of the total genetic contribution to liability. The most consistently replicated area of the genome contributing to liability to schizophrenia is the major histocompatibility complex on chromosome 6. This is a highly complex genomic area that is naturally prone to rearrangement, but it lends support to the notion that there may be an immunomodulatory component involved in the etiology of schizophrenia.

SNPs only represent one type of genetic variation (although associations seen with SNPs may 'tag' other types of variation). The role of copy number variants (CNVs) has also been investigated. CNVs refer to deletions or duplications of genomic material, usually less than 3 million base pairs in size (above this size, duplications and deletions of genomic material can usually be seen under the light of microscope in a standard cytogenetic analysis). Rare CNVs (occurring in less than 1 in 100 individuals) have been robustly associated with autism, hence attention has turned to the possible role these variants might have in schizophrenia. While the studies of copy number variation are in their infancy in comparison to SNPs, early evidence suggests that rare CNVs are seen at an increased frequency in schizophrenia, although the same variants are also seen in cases of autism, epilepsy, and learning disability, along with healthy controls (at a reduced frequency). This observation underlines the clinical heterogeneity that may result from observed genetic variation. This probably reflects both the conceptual 'distance' between observed genetic variation and clinical diagnostic categories and also the relative contribution of other genetic variants within a case that happens to contain a rare variant.

The most frequently observed CNV in cases of schizophrenia is a deletion of 3 million base pairs in the long arm of chromosome 22. This is an area of recent evolutionary rearrangement, and probably under high selection pressure. The deletion is also seen clinically in the velocardiofacial syndrome, DiGeorge syndrome, autism, affective disorders, and in the normal population. Again this underlines the clinical heterogeneity of any observed genetic variant and emphasizes the concept of genetic penetrance.

It can be concluded from this evidence that there is no single causal or major gene that explains the genetic liability to schizophrenia. Both rare and common variants contribute to genetic liability, which will vary between individuals. We probably all carry a degree of risk to developing schizophrenia, with this degree of risk approximately normally distributed among individuals in the population. In this sense, the disorder is a very human one, with the idea that we all carry a risk for the disorder serving, perhaps, as a basis for reducing stigmatization in mental disorders. Such an observation also means that the selective breeding policies employed by the eugenics movement would never have worked to breed out liability for schizophrenia (or any complex disorder), and also explains why the prevalence of schizophrenia has remained stable over time, even though sufferers show reduced fecundity. It also means that the underlying biology of the disorder is likely to be variable between individuals. This appears, at least partially, consistent with the clinical picture, in which no one sign or symptom is either necessary or sufficient to result in a diagnosis, and that the disorder can occur at any age. Similarly it explains why sub-threshold signs of the disorder are seen at an increased frequency in the relatives of probands, and why sporadic cases of schizophrenia are seen in families with no prior history of the disorder. Both common and rare variants contribute risk, but very few individuals will have genetic variants that are, individually, associated with any substantial risk for the disorder. The best example of a rare variant contributing to risk of schizophrenia is the 22q11 deletion, however even with this large deletion of many genes a spectrum of disorder exists, from normality to profound disability. It is likely that genetic variants act both individually and in concert to produce both a risk of, or a resilience to, any particular disorder, and the environment is also critical in determining whether this risk results in clinical manifestation of a diagnosis.

Affective Disorders

The affective disorders are characterized by single or recurrent bouts of clinically significant mania, depression, or both. Traditionally recurrent bouts of mania and an alternation between manic and depressive states have both been considered under the diagnosis of bipolar affective disorder (BPD) with single and recurrent depressive states without mania considered under the major depressive disorder (MDD) diagnosis. Manic states are characterized by lack of need for sleep, extreme irritability or elation, racing thoughts, pressure of speech and ideas, thought disorder, disinhibited and socially inappropriate behavior, grandiose delusions, and lack of insight. Depressive states are characterized by low mood, anhedonia, disturbed sleep and appetite, low energy levels with amotivation and psychomotor retardation, poor concentration and decision-making abilities, a strongly negative cognitive bias including suicidal thoughts and acts, prominent comorbid anxiety, and, in severe cases, depressive delusions and hallucinations. Insight is usually preserved in all but the most severe depressive states. Mixed affective states occasionally occur, as does a syndrome of recurrent distinct psychotic and affective episodes, which is often classified as schizoaffective disorder. The lifetime prevalence of BPD is approximately 0.5–1.5%, whereas this rises to estimates of between 4 and 17% for MDD, which is also seen more often in females. The wide range of estimates for lifetime prevalence in MDD is largely attributable to the clinical definition used, with milder forms of the condition much more prevalent than more severe types as well as having clear overlaps with the normal processes of grief, sadness, and loss.

Twin Studies

The familial aggregation of mood disorders has been noted for over 100 years; however, there are clear differences between BPD and MDD. Within formal family studies, the first-degree relatives of probands with MDD are about three times more likely to suffer from the disorder than controls, whereas this figure rises to about eight in BPD. Mean monozygotic concordance rates are 30–70% for unipolar depression and 50–80% for bipolar disorder. Dizygotic concordance rates are 10–30% for unipolar depression and 10–20% for bipolar disorder. The calculated heritability rates are 30–50% for unipolar depression and 50–80% for bipolar disorder, the figure calculated being highly dependent on the severity of sample analyzed, but even in the severest samples leaving considerable space for environmental risk factors (Sullivan et al., 2000). A graduation of risk is seen as genetic distance from the proband increases; however, the etiological and clinical heterogeneity of affective illness probably precludes estimates that are generalizable to a large proportion of sufferers. This can confound attempts to combine different samples of affective disorders together to study the genetic basis of liability to disorder, as even more clinical heterogeneity is introduced into an already notoriously heterogeneous group.

Interestingly, the familiality of affective illness is not bidirectional. The relatives of probands with BPD have a much higher risk of developing both BPD and MDD. However the relatives of probands with MDD do not carry a higher risk of developing BPD. This argues for a partial genetic overlap between MDD and BPD, but suggests that BPD in particular has a proportion of unique genetic liability. The picture is further complicated, by the fact that the relatives of probands with BPD have a higher chance of developing psychotic disorders such as schizophrenia, although not as high as relatives of probands with schizophrenia. Relatives with probands of schizophrenia have a higher chance of developing MDD, and the reverse also appears to be true (but to a much lesser extent). Put simply, there appears to be a complex overlapping genetic liability between clinical subtypes of mental disorders and there may be a common liability to mental disorder that transcends traditional diagnostic boundaries.

Molecular Genetics

Given the relatively high lifetime prevalence of unipolar depression in the general population, informative longitudinal studies exploring the relationship between different risk factors from various domains are feasible. A population-based prospective twin study (Kendler, 1990) proposed that genetic and environmental risk factors (such as early parental loss, perceived parental warmth in childhood and critical life events, and social support later on) interact. The risk factors occurring already in childhood also influence personality features (e.g., neuroticism) and coping strategies that also operate as risk factors for depression and mediate the early environmental and genetic sources for the final disease status. A particularly noteworthy example of a specific gene–environment interaction in MDD was demonstrated by Caspi et al. in a paper published in 2003 (Caspi et al., 2003). The results from the study suggested that those who carried a particular form of the promoter for the gene that encodes the serotonin reuptake transporter on presynaptic neurons (*SERT*) were more vulnerable to developing MDD in the presence of stressful life events, than those who had the other form of the promoter. A plausible result from many perspectives, this result has nonetheless been hotly debated for over 10 years, with different studies providing both replication and non-replication of the result. The evolving consensus suggests that the effect is probably real although the authors may have been subject to the so-called 'winner's curse' (the tendency toward overinflation of effect size in novel findings, for a variety of reasons).

Caspi et al.'s work is a good example of a 'candidate gene study.' Such studies start with a hypothesis (in this case that genetic variation in the serotonin transporter may moderate the liability to develop MDD in response to stressful life events) and tailor the experiment to provide data that will confirm or refute it. This is in particular contrast to GWAS, which are 'hypothesis free.' GWAS interrogate huge numbers of sites on the genome and test each for association with disease. Because they are 'genome-wide' experiments (i.e., testing variants from across the genome) they come with no prior assumption that any particular variant is more likely than any other to be associated. While this hypothesis-free approach is intuitively attractive because it frees research from the subjectively biased hypotheses of the researching team, statistical issues resulting from a lack of power to detect what are small individual effects of any one variant require sample sizes that are so huge that they test the limits of practicality.

To this extent, the results of GWAS in affective disorders have been less exciting than in psychotic disorders such as

schizophrenia. Again, this probably denotes the highly heterogeneous nature of the disorders, both at a clinical and biological level. In support of this, candidate gene studies in affective disorders have generally reported inconsistent results and linkage analysis was also inconclusive, with no replicated findings standing the test of time and scrutiny by the research community. GWAS in BPD have identified one SNP that replicates consistently, and others are showing signs of association as samples are combined into larger and larger datasets. The one robustly identified SNP is in the gene *CACNA1C*, which encodes a subunit of a major neuronal calcium channel found in the brain (Craddock and Sklar, 2013). This is of great interest, since calcium channel moderating drugs (such as the antiepileptic drug lamotrigine) are widely used to treat both BPD and MDD. This represents the first example of a plausible marriage between the clinical reality of the disorder and the underlying biology and genetics. However, while there was initial excitement over genome-wide significant findings in MDD, a recent mega-analysis with 9240 cases and 9519 controls, revealed no significant associations (Ripke et al., 2012). However even at this sample size, it is likely that the lack of findings is probably due to inadequate statistical power to detect an effect. In MDD, where the prevalence is relatively high and the clinical and genetic heterogeneity also high, sample sizes in the order of hundreds of thousands, or even millions, of individuals may be needed.

Conclusion

In 1967, Gottesman and Shields wrote, in an attempt to harmonize what, at that time, was a substantial split between the psychiatric and biometric view of schizophrenia:

> One of the possibilities not given sufficient attention involves positing a large proportion of cases as being polygenically determined. We should like to consider the merits of treating schizophrenia as a threshold character whose appearance is predictable from a diathesis-stress model …. Let us suppose that the diathesis is polygenically determined and that what is inherited is a constitutional predisposition to developing schizophrenia …. Although schizophrenia is necessarily viewed as an all-or-none character for record keeping purposes, clinical contact with preschizophrenics or 'recovered' cases shows clearly the artificiality of such a dichotomy …. Falconer has now made available a model and methods for the handling of disease incidences in the relatives of probands with threshold characters, i.e., diseases that appear to have an all-or-none manifestation but are in fact determined by an underlying graduation of some attribute really causing the disease. The latter attribute has been termed liability by Falconer and is intended to convey not only the individual's innate tendency to develop the disease (i.e., susceptibility), but also the environmental milieu to which he is exposed that makes him likely to develop the disease.
>
> Gottesman and Shields, 1967

The latest evidence suggests not only that their opinion was, broadly speaking, correct but that such an etiological framework may be applied to a broad range of common, complex disorders. As such, a reductionist approach probably has very little place in the consideration of the genetic basis for liability to psychiatric disorders. The replicable genetic associations with psychiatric disorders reported here represent the first steps on what is likely to be a long and difficult path to the understanding of etiology and pathogenesis. Effect sizes for individual variants are likely to be small, except for a small minority of cases that harbor rare variants that confer a relatively high degree of risk.

All common psychiatric disorders display a complex genetic heterogeneity, meaning that multiple partially overlapping sets of genes, themselves in a complex interaction with the environment, can predispose to similar syndromes that are currently indistinguishable on clinical grounds. There may be a common liability to psychiatric disorders in general, rather than individual disorders specifically. There still exists a vast conceptual gap between the clinical reality of common psychiatric disorders and the demonstrable, replicable science, but progress toward understanding the basis of genetic liability to these disorders is slowly being made. Whole genome sequencing efforts, which can detect still more variants that may contribute to risk or resilience are currently underway and firmer conclusions from this data should be available in the next decade or so. We should no longer expect the quest to uncover the genetic liability to complex disorders, especially mental disorders, to be simple.

In summary, the genetics of mental disorders has a long and sometimes controversial history. Currently, only rare variations of mental retardation and early onset Alzheimer's disease have been demonstrated to be classical genetic diseases with mutations at one gene locus causing the clinical syndrome (monogenic diseases). Most mental disorders are highly prevalent in the general population. Such common mental disorders share a series of features with common diseases such as hypertension, cardiac disease, and type 2 diabetes mellitus:

1. All common mental disorders are familial (i.e., relatives of patients are more likely to be affected with the same disorder than random subjects in the general population).
2. Twin studies performed for all common mental disorders point to a substantial genetic component, which is probably best conceptualized as a liability to develop the disorder in the presence of precipitating and perpetuating environmental factors.
3. The concordance rate among monozygotic twins is far from 100%; thus, the etiology is multifactorial with environmental as well as genetic factors contributing.
4. The phenotype as transmitted in families is variable between relatives; unlike monogenic diseases a clear distinction between affected and healthy individuals is impossible.
5. The familial aggregation of one disorder often goes together with the co-aggregation of another disorder (e.g., generalized anxiety disorder and depression); a common genetic liability may account for this co-aggregation in families.
6. The genetics of each common mental disorder is complex and associated with genetic heterogeneity; the genetics does not follow a clear Mendelian mode of transmission, but genome wide association studies argue for the contribution of multiple genes to each disorder. Consequently, the contribution of a single genetic variant is not causal, but only probabilistic (susceptibility genes influencing the risk of the disorder).

7. Multiple susceptibility genes for a disorder may either emerge from multiple monogenic, clinically indistinguishable subtypes or from the simultaneous and cumulative contribution of many genes. While the first possibility cannot be excluded definitively, the second possibility is substantially more plausible given the lack of Mendelian transmission. While the contributing genetic variants are likely to be rare under the first condition, the contrary should be the case under the second condition. Each of these common genetic variants is likely to be of ancient origin, dating back about 100 000 years. The functional consequence of each variant is presumably modest, which explains the persistence of the variants despite evolution by natural selection. In contrast, rare genetic variants causing monogenic diseases are more recent in origin, confer much reduced fecundity, and are therefore, presumably, under strong negative evolutionary selection pressure.
8. The first replicable glimpses of genetic variation associated with common, complex mental disorders have been established, but the picture is more complicated than many imagined and the technical challenges in unpicking the relative contribution of different genetic variants contributing to mental disorders are daunting. Slow but steady progress is being made, and advances in molecular genetic techniques over the past 20 years particularly have been spectacular. An explosion of new genetic data since the completion of the human genome project has led to both renewed hope and new challenges, in the field of psychiatric genetics.

Abstract

Organizations focusing on the concerns of users and families operate at a number of levels, global, national, and within individual countries. This article describes one regionally based organization, the European Network of (ex-)Users and Survivors of Psychiatry. Organizations work in a number of different ways, and have developed different models of linking with statutory services. The benefits of belonging to a family organization are reported, as well as the development of self-help groups.

Mental Health Policies and the Family

In November 1999 Dr Gro Harlem Brundtland, director general of the World Health Organization (WHO), launched the WHO's new global strategies for mental health. These strategies aim to ease the 'burden' of mental disorders and neurological diseases currently affecting about 400 million people, by improving the quality of care throughout the world, particularly in the developing countries.

WHO aims to achieve these objectives through a number of measures in both developing and developed countries. The organization plans to raise awareness of the relative importance of mental disorders as a major contributor to the global burden of disease in different groups, including health professionals and public health decision makers, and also among the general public. WHO will fight the social stigma, misconceptions, and discrimination associated with mental illness, as well as promote the human rights of people with a mental illness: "Very often and in many countries, individuals who are affected by neuropsychiatric disorders endure double suffering, namely from the conditions themselves and from the social stigma and discrimination attached to them" (WHO/67 Press Release, 21 November 1999 – Raising Awareness, Fighting Stigma, Improving Care). In December 2001, the 10th anniversary of the Principle for the Protection of Persons with Mental Illness and the Improvement of Mental Health Care adopted by the UN General Assembly in 1991, Dr Brundtland proposed launching measures to foster the implementation of these principles with, for example, an International Convention on the Rights of Persons with Mental Disorders.

Mental health promotion should go beyond simply achieving the absence of a mental disorder, but aim to improve mental well-being, a state in which individuals can realize their abilities, cope with the stresses of life, work productively, and make a positive contribution. WHO has identified poverty as a great obstacle to such mental well-being. In both mental health promotion and in treatment and care Dr Brundtland saw the family, often extended by the closest community network, as having a central role to play: "Much of the burden of caring for the mentally ill, or for prevention for those who are in danger of becoming ill, is left to the family…" (Office of Director General, WHO, 13 October 1999). The family needed more support and better information, in recognition of their work. She commended the 1995 'Barcelona Manifesto,' put forward by the European Union Federation of Family Associations of Mentally Ill People, which outlines the needs and perceived rights of the family of a person with mental illness, and would consider its principles in WHO's work.

At a regional level, within the European Union, the Council of Ministers of Health has also focused on mental health, in particular the promotion of mental health within the context of improving social inclusion. It has invited the European Commission to analyze the impact of community activities on mental health, for example, in the fields of education, youth policy, social affairs, and employment, and to consider the need to draw up – after consulting with member states – a proposal for Council recommendations on the promotion of mental health in the European Union.

User and Family Organizations Related to Mental Illness

There are organizations focusing on users and families' concerns operating at a number of levels: global, regional, national, and within individual countries. Some organizations are run by users for users, while others involve mental health professionals. At a global level, the World Association for Psychiatric Rehabilitation and the World Federation for Mental Health each has an interest in the perspective of users and carers.

An example of an user-run organization at a regional level is the European Network of (ex-)Users and Survivors of Psychiatry, which describes itself as "a regional initiative to give (ex-) users and survivors of psychiatric services a means to communicate, to exchange opinions, views, and experiences in order to support each other in the personal, political, and social struggle against expulsion, injustice, and stigma in our respective countries."

The history of the network goes back to 1990 when an initiative was taken in the Netherlands to form a network of associations of (former) psychiatric patients from various European countries. Since then the network has organized four

European conferences. At the last conference in Luxembourg in 1999, more than 90 delegates, all of them (ex-)users/survivors from 26 European countries, met and created an action plan for the coming years.

The aims and objectives of the European Network are:

1. The European Network is against any unilateral approach to, and stigmatization of, mental and emotional distress, madness, human suffering, and unconventional behavior.
2. The European Network should support (ex-)users/survivors' autonomy and responsibility in making their own decisions (self-determination).

Priorities for the network include the following:

1. Act against any kind of discrimination in society (both inside and outside the mental health care system) of people who have been subject to the psychiatric system.
2. Support the development of (ex-)user/survivor groups throughout Europe (with a particular emphasis on those countries where there are no existing organizations).
3. Create and support new alternatives to the psychiatric system and collect and share information on the existing ones.
4. Influence and try to change present treatment in psychiatry.

The European Network attempts to influence policy at a European level and maintains contacts with other international organizations active in the mental health field. The network collaborates with the WHO Regional Office for Europe, the European Union, the European Disability Forum, the International Labour Organization, Mental Health Europe/Santé Mental Europe (the former European Regional Council of the World Federation for Mental Health), and the Geneva Initiative on Psychiatry.

The network is a federal structure of national and local associations of (ex-)users and survivors and of mixed organizations with a significant (ex-)user/survivor membership. For countries where there are no such associations, exceptionally individual (ex-)user/survivor members may become members. The aim is for the network to be a grassroots, democratic, and fully (ex-)user/survivor-controlled organization. Through the membership of its member organizations the network represents several tens of thousands of (ex-)users/survivors from across Europe.

In the USA during the last 20 years the National Alliance for the Mentally Ill (NAMI) has grown, with a membership now of over 200 000 family members and service users. It operates at a national, state, and local level to 'provide the nation's voice on mental illness.' It represents family members and service users who seek more equitable services for people with a severe mental illness.

In Europe, voluntary organizations from a number of countries, which represent the relatives of people with a mental illness, came together in DeHaan, Belgium in 1990. A manifesto signed by family associations from 10 European countries led to the establishment of the European Federation of Associations of Families of Mentally Ill People in 1992. At their third congress held in Sweden in 1999, 22 member associations from 15 countries – directly representing 55 000 families – set out their aim to work toward the reduction of stigma and discrimination against people with a mental illness and to seek adoption by health professionals of the highest standards of good practice.

Function of User and Family Organizations Related to Mental Illness

There are some descriptions of individual groups and programs available. One group focuses on issues of loss and how to overcome it (Baxter and Diehl, 1998). The BRIDGES program and the Journey of Hope are peer-taught programs that offer education and support to people with a severe mental illness and their families. The aim is to validate the participants' sense of loss as normal, and provide a structure for a new sense of self, so that individuals and their families can move from isolation and loneliness to empowerment and reconnection with ordinary life.

Families of people with dementia may have particular needs given the progressive nature of the illness and its increasing impact on carers as a person's mental and also physical health declines. Support groups for carers allow members to trade information about the disease and daily care requirements (Wormstall et al., 1996). Around the globe there are many voluntary organizations dealing with mental health issues in general or specific psychiatric disorders such as depression, eating disorders, or suicide. Each of these have specific remit and national charity laws and regulations apply to them.

The Relationship between Family Organizations and Statutory Services

Members of family organizations may be dissatisfied with the care provided by statutory services. Members of the Dutch organization Ypsilon, which supports the relatives of people with a long-term psychotic illness, took part in a questionnaire study. They reported a lack of access to treatment professionals, a lack of information about their relative's illness, and a lack of family involvement in treatment planning (Schene and van Wijngaarden, 1995).

In some family organizations, health professionals may be more involved. In Massachusetts, Alliance for the Mentally Ill (AMI) provides eight family support groups, with a total average monthly attendance of 86 relatives and 25 professionals (Bouricius et al., 1994). Family members lead the groups, but they encourage health professionals to attend. Results of a questionnaire given to the relatives showed that a large majority found the attendance of professionals at the meetings to be helpful in accessing needed services. The researchers also reported that the support groups tend to improve services for people with a mental illness in the area.

Across the USA there is a wide variation in the contact between doctors training in psychiatry and psychoeducational programs involving families of people with a mental illness. In less than half of the psychiatry training schemes is NAMI formally involved. Barbee et al. (1991) give some examples of successful collaboration. In one program, an exercise in which trainee psychiatrists and family members change roles is recommended for its ability to improve communication between trainees and families.

Such programs may have some effect in reducing the delay between a person being diagnosed as having a mental health problem, and family members getting in touch with a support organization. A survey in Quebec of AMI members found that half of the members experienced a delay of over 2 years and only 10% were referred to the organization by a psychiatrist (Looper et al., 1998). The majority of respondents would have preferred earlier contact, and some approved of the more proactive methods developed by AMI-Quebec such as a telephone call after a relative's first admission to hospital.

Benefits of Involvement with a Family Organization

There is some evidence of family members gaining benefit from joining a support group. For example, in a study of 225 families with a relative with a mental illness, there were significant differences between those who participated in a support group and those who did not (Mannion et al., 1996). The support group participants were more likely to be a parent with a higher functioning relative who had been ill for a longer time. They reported less subjective burden and a greater use of adaptive coping mechanisms than did members of families who did not participate in a support group.

It is possible to demonstrate that there are some ingredients of a group that are particularly helpful. A US study compared two types of group, an interactive psychoeducational model and a support model offering nonstructured discussions (Kane et al., 1990). Each was held over four sessions for the families of people with a relative with schizophrenia or schizoaffective disorder. In the psychoeducational group, over three-quarters of the participants rated the quality of the information received as excellent, and 94% said they had received the kind of information they wanted. This compares with a quarter of the support group rating the information as excellent and none feeling that they had received the help they wanted. There was a lower level of depression in members of the psychoeducational group.

A study in Germany reported benefits for family members who joined a self-help group (Schulze-Mönking, 1994). In this case the families of men with a severe mental illness were most likely to join the group. Over the 2 years of the study, there was a tendency for the relatives of the families which participated to have a better outcome. Family members in the group developed more social contacts and reported fewer physical complaints.

As well as providing support and information about a relative's illness, these organizations can fulfill a number of other functions. For example, in the Circle Model, family members caring for a relative who is cognitively impaired are enabled to get some respite (Jansson et al., 1998). Equal numbers of family members and volunteers train together in a study circle, and once trained, the volunteers can replace the carer on a regular basis in the person's home. The relatives gained support from meeting others in the same position as themselves, and they also expressed feelings of security and relaxation in relation to their respite from the home situation. The volunteer caregivers also expressed satisfaction and appreciation of the knowledge they gained from the caregivers.

In many caregiving situations, an elderly parent is looking after a grown-up son or daughter at home or providing substantial amounts of support out of the home. One of the biggest worries for the carer may be what will happen after his or her death. The Planned Lifetime Assistance Network is available in some parts of the USA through NAMI. It aims to provide lifetime assistance to individuals with a mental health problem whose parents or other family carers are no longer alive, or are no longer able to provide care (Lefley and Hatfield, 1999).

Another area of growth outside the statutory sector is in self-help groups in the voluntary sector. Their focus is diverse and represents an interest in promoting self-help and support for people with a range of mental health problems including anxiety disorders, mood disorders, schizophrenia, and dementia. These groups are created and operate at a local, regional, and national level. Some have developed groupings at an international level whose main focus is to act as a lobby group and advocate for intergovernmental initiatives in policies around mental health.

Self-Help Groups

In the USA, Borkman (1997) has linked the development of contemporary self-help groups with the founding of Alcoholics Anonymous (AA) in 1935. AA is a model for other self-help groups, which are also nonhierarchical direct democracies that avoid advocacy but focus on providing support. The major growth of all these groups took place during and after the 1970s alongside the development of the civil rights and women's movements, both of which challenged bureaucracies and traditional authority.

To understand more about the people involved in self-help groups, Chamberlin et al. (1996), using a participatory action research paradigm, with an advisory committee of individuals who had used such a program, carried out a survey of participants in six representative programs. Respondents spent an average 15 h per week in their program and had been attending for almost 5 years. Members both received and gave help. Overall they reported that attending a self-help program had a salutary effect on their quality of life.

Other organizations controlled by consumers or survivors may have different aims, carrying out different activities. Trainor et al. (1997) define consumer/survivor organizations as being operated for and controlled and staffed by people who have used the mental health system. In Ontario, Canada, the Consumer/Survivor Development Initiative funds 36 such organizations. They carry out a range of activities, which include offering mutual support, cultural activities, advocacy skills training, and education for the public and professionals. Involvement in a self-help group leads to a drop in contact with services, with less time spent in inpatient care, and less contact with crisis services, suggesting that contact with such groups may help individuals handle difficulties in a different way.

In the UK information from members of different user groups suggested that these groups could have a role in ensuring that individual users' rights were respected (Barnes and Shardlow, 1997). They also enabled people with a mental health problem to improve the accountability of

services and supported their wider participation as citizens. Working with families and across social and health care is one way forward for delivering mental health services in the twenty-first century (Bhugra and Carlile, 2013). Resilience can be improved by involving families and other stakeholders (SPN, 2007; Friedli, 2009). Patients are at the center of the therapeutic interactions but they are surrounded by families, employers, society, and others and a truly multipronged approach is needed.

Abstract

Mental imagery can be defined as a quasi-perceptual experience occurring in the absence of perceptual input. The present article provides a review of the key processes involved in mental imagery, the relationship of imagery to working memory, and of the debate on the underlying format of mental images. We also review the functional significance of imagery in a range of cognitive processes, such as memory, creative thinking, reasoning, and problem solving. Finally, the brain basis of mental imagery and its overlap with the cortical regions involved in visual perception are discussed.

What Is Mental Imagery?

Mental imagery has been the subject of debate for millennia. Philosophers in Ancient Greece, who argued that "the soul never thinks without a mental image" (Aristotle, De anima 431a 15–20), described mental images as either impressions stamped on wax by thoughts and percepts (Plato, Theatatus 191c,d) or pictures painted in the soul by an inner artist (Plato, Philebus 39c). Mental imagery can be defined as a quasi-perceptual experience occurring in the absence of perceptual input (Rinck and Denis, 2004). It refers to internally generated conscious experiences and is often described as 'seeing in the mind's eye,' 'hearing in the head,' and 'imagining the feel of' (Kosslyn, 1994; Kosslyn et al., 2006). Mental images can be created from information held in long-term memory (LTM) or from recently presented sensory information.

One of the first modern empirical investigations on imagery was carried out in Edward B. Titchener's laboratory at Cornell University by one of his postgraduate students, Mary Cheves West Perky (1910). In her experiments, observers were asked to fixate on a glass screen on which they were required to project mental images of various objects. Unknown to the observers, visual stimuli were back-projected onto the screen while they were engaged in imagery. In almost all cases, the observers were unaware of these stimuli even though in the absence of imagery they were easily detected, indicating that mental images impaired the encoding of concurrently presented external sensory input. However, although the Perky effect is often described in terms of masking of visual input by mental imagery, one of its key features is the merging of internally generated percepts with externally presented information. For example, when participants were asked to imagine a banana in an upright position, the subliminal presentation of a banana in horizontal position modulated the participants' experience of their mental imagery such that they were more likely to report the orientation of the visual stimulus, rather than what they had been asked to imagine. A further fascinating example was provided by the studies of Sydney Segal (e.g., Segal and Gordon, 1969). In one of Segal's experiments, when observers were asked to imagine the New York skyline, they tended to describe imaging the skyline at sunset when a uniform red color was presented on the screen. This aspect of the Perky effect has been recently replicated in a psychophysical paradigm, and it is informative of how mental imagery can be distinct from memory content (Bona et al., 2013). Fundamentally, the Perky effect is theoretically important because the ability of visual input to merge with mental images indicates that the latter calls upon mechanisms that are engaged in the perception of externally presented visual information.

The Imagery Debate (the Analog-Propositional Debate): What Is the Representational Format of Mental Images?

The representational format of mental images has been perhaps the most hotly debated topic in the study of visual imagery. The debate has focused on two competing theoretical viewpoints: the *pictorial* (or *depictivist*) *theory* (Kosslyn, 1994; Kosslyn et al., 2006) and the *propositional* (or *description*) *theory* (Pylyshyn, 2003). According to the depictivist viewpoint (Kosslyn et al., 2006), mental images are representational brain states that are genuinely 'picture-like.' This view is supported by the classic experiments on mental rotation (e.g., Shepard and Metzler, 1971) and mental scanning (Denis and Kosslyn, 1999; see **Figure 1**). In the seminal study of Shepard and Metzler (1971), participants were asked to judge whether two figures that varied in their degree of rotation were the same or different. In order to perform the task, participants presumably needed to use imagery to rotate the figures such that they were in the same orientation. The key finding was that the time taken to perform the task correlated with the angle of rotation by which the two objects differed, consistent with the view that, if the representation is pictorial, rotation of a larger angle is more time-consuming. Similar results were obtained in mental scanning experiments, in which participants had to memorize locations on maps or figures and were asked to mentally scan the path from one location to another. The amount of time required was directly proportional to the distance between the two locations, as if the participants were scanning a physical map with their eyes (Borst and Kosslyn, 2008). These results led to the conclusion that mental images are 'picture-like.'

According to the propositional (or descriptive) view (Pylyshyn, 2003) there is nothing 'picture-like' in the underlying format in which mental images are represented. In this view, the conscious experience of mental imagery is an epiphenomenon

Figure 1 (a) A sample mental rotation task (from Shepard, R.N., Metzler, J., 1971. Mental rotation of three-dimensional objects. Science 171(972), 701–703). Reprinted with permission from AAAS. (b) Scanning mental maps (from Kosslyn, S.M., Ball, T.M., Reiser, B.J., 1978. Visual images preserve metric spatial information: evidence from studies of image scanning. Journal of Experimental Psychology: Human Perception and Performance 4 (1), 47–60). Reprinted with permission from APA.

since they are not indispensable for having an internal representation of an object or a scene. Rather, mental images involve the same forms of representation as reasoning in general; that is, propositional representations consisting of an abstract system of symbols, which can be used to express the contents of the mind. According to the propositional view of mental imagery, many findings used in support of the pictorial view can be accounted for in terms of participants' 'tacit knowledge' of the external visual world. Specifically, Pylyshyn argued that "[…] nearly all experimental findings cited in support of the picture theory can be more naturally explained by the hypothesis that when asked to imagine something, people ask themselves what it would be like to see it, and they then simulate as many aspects of this staged event as they can and as seem relevant. I refer to this explanation as the 'null hypothesis', because it makes no assumptions about format – it appeals only to the tacit knowledge that people have about how things tend to happen in the world, together with certain basic psychophysical skills" (Pylyshyn, 2003).

The imagery debate has been difficult to resolve; however, recent findings from neuroimaging studies have shed new light on the issue. These findings will be reviewed in the last section.

Mental Images Generated from Short-Term Memory versus Long-Term Memory

The classic work of George Sperling (1960) demonstrated that our perceptual system stores a large amount of visual information for approximately 500 ms beyond the presentation of the target stimuli. This memory storage is referred to as *iconic memory*, and it is sometimes confused with mental imagery. The key difference is that, in contrast to iconic memory traces that are somewhat automatic and closely reflect bottom-up visual input, mental images are thought to result from (wilful) top-down processes. Furthermore, mental images can be generated from information held either in LTM or from STM (short-term memory); in the latter case, briefly after the presentation of the to-be-imagined item. For example, participants may be asked to generate a mental image from verbal instructions (e.g., 'imagine an apple'), in which case the image needs to be retrieved from LTM and involves the transfer of verbal information into a visual representation (cf Baddeley, 2007). In contrast, when participants are asked to form an image from visual information (e.g., when they are presented with a picture of an apple and then asked to imagine it beyond the presentation of the visual cue), no transformation is required as the mental image can be based on the representation held in visual working memory (WM). The latter is likely to retain all the features of the cue on which the mental image is based, whereas the former could be conceptualized as a basic prototypical representation of an object. In this vein, a taxonomy of mental images has been suggested, with a distinction between *general* and *specific* images. When mental images are created from LTM, performance in mental scanning paradigms is inferior (reflected as slower reaction times) relative to images based on recently presented visual information. This may be because mental images generated from LTM are akin to 'degraded' iconic images. Thus slower scanning with images generated from LTM would reflect difference in 'vividness' between images generated from LTM and "vivid" images generated from recently encoded perceptual input. Also, mental images generated from LTM may be more fragmented than those generated based on STM content, with the scanning process filling in missing material (Borst and Kosslyn, 2008).

Imagery in Models of Working Memory

In Kosslyn's view (1994; Kosslyn et al., 2006) potential mental images are stored in LTM as 'deep representations,' defined as structural descriptions not directly accessible to awareness. These can be used to generate the actual depictive-analogical images in the so-called *visual buffer*. An analogy can be made with a computer program: data are saved in specific files (analogous to the 'deep representations' stored in LTM) from which pictures can be generated on the computer screen. In this view, the computer screen is analogous to the visual buffer, where information becomes available to consciousness and can be analyzed by the 'mind's eye.' Kossyln (1994; Kosslyn et al., 2006) suggested that visual imagery and visual perception draw on many of the same cognitive processes and representations, and recruit broadly the same brain areas, including the primary visual cortex (see below). Topographically organized visual areas would be grouped into a single functional structure, the visual buffer, representing the medium that supports mental images. Once formed, mental images fade in few hundred milliseconds, corresponding to the time required to initiate and carry out an eye movement (Kosslyn, 1994); thus, active maintenance is required for imagery to last sufficiently long for it to be inspected. In Kosslyn's view, this is accomplished by the reactivation of visual memory representations in an object properties-processing subsystem (Kosslyn et al., 2006).

Even with active maintenance, holding a mental image for more than a few seconds in the 'mind's eye' is challenging (Cocude and Denis, 1988). This may be because mental images rely on the same visual areas of the occipital cortex that underlie visual perception (Kosslyn et al., 2006) and, consequently, there is mutual interference between visual imagery and visual perception (e.g., Baddeley and Andrade, 2000; Quinn and McConnell, 2006). However, imagery can nevertheless be efficiently carried out while the visual system is receiving visual input and there are no consistent differences in the reported vividness of images experienced under 'eyes-open' and 'eyes-closed' conditions (Isaac and Marks, 1994). Image maintenance is thought to depend on attentional resources that can become rapidly depleted (Logie, 1995; Pearson et al., 2001); studies have shown mental images maintenance to highly tax general-purpose attentional resources involving the central executive component of the WM system (Pearson et al., 1996).

In a parallel line of research, Baddeley (2003, 2007) considered mental imagery as a function of the WM network (see also Logie, 1995). Baddeley proposed that "… working memory … temporarily maintains and stores information, supports human thought processes by providing an interface between perception, long-term memory and action" (Baddeley, 2003: p. 829). The multi-component model of WM emphasizes the operational capacity of the system (hence the name *working* memory), in contrast to previous models that conceptualized memory as primarily a storage facility. In Baddeley's original model, a key component of WM is the *visuospatial sketchpad*, dedicated to storage and maintenance of visuospatial information and mediating both the retention of perceptual information and mentally generated images. When a mental image is generated from visual input, it can be directly mapped into the *visuospatial sketchpad*. In contrast, when visual mental images need to be generated from verbal cues, retrieval from LTM with the aid of phonological loop (the *verbal* component of the WM system) is required (Baddeley, 2007). Cornoldi et al. (1998) distinguished between visual traces and generated images on the basis of the degree of attentional requirement, voluntary manipulation, rehearsal mechanisms, and capacity limitation associated with them.

Subsequent models, motivated by Baddeley's theory, have conceptualized the visuospatial WM system as a multi-component mental workspace, with distinct components playing key roles in visual imagery and visual short-term retention (VSWM; Logie, 1995, 2011). According to the VSWM model, the generation of mental images requires the activation of stored knowledge about the stimulus; in addition, executive functions involved in processing and manipulating the activated knowledge are necessary. Image generation requires an active store (visual buffer) that is proposed to use brain structures involved in visual perception, such as the primary visual areas in the posterior occipital cortex (Kosslyn et al., 2006; Kosslyn and Thompson, 2003). Because this active store uses resources involved in visual perception, it is sensitive to disruption from irrelevant visual noise. However, the actual retention of both visual information and mental images occurs in a passive VSTM store or visual cache (Logie, 1995). There is evidence in support of this view: once the mental image has been generated, it is not susceptible to irrelevant visual input (Borst et al., 2012, but see Bona et al., 2013).

Imagery and 'Visual' Cognition

Imagery has been shown to play a facilitatory role in a number of cognitive functions such as learning, memory, reasoning, mathematics, and creative thought. Thus, imagery is functionally beneficial in a range of cognitive functions. These will be reviewed below.

Learning and Memory

The beneficial contribution of mental imagery to memory has been known for centuries, and mnemonic techniques involving imagery were used already in the ancient times (Yates, 1966). As reported by Cicero (106–43 BC), it was the Greek poet Simonides (*c*.556–*c*.468 BC) who first discovered the powerful mnemonic properties of imagery. As the story goes, Simonides was attending a banquet in Thessaly in order to present a poem in praise of his host. After his speech, Simonides was called outside and, during his short absence, the roof of the banqueting hall suddenly collapsed. Simonides was able to identify the victims on the basis of where their bodies were found by creating from his memory a mental image of the diners sitting around the banqueting table. From this tragic event, Simonides concluded that the creation of a mental image in which the items to be remembered are linked to specific locations is an efficient way of facilitating memory (Cicero, *De Oratore*, II, lxxxvi); this technique is known as the *method of loci*. As described by Cicero and Quintilian (AD *c*.35–*c*.95), it was originally

employed by speakers to retrieve passages of their speech in the correct order. The English phrases 'in the first place' and 'in the second place' originate from this technique.

In modern psychology, the dual coding theory of memory proposed by Allan Paivio (1991) provides a theoretical framework for the mnemonic benefits of imagery. In this model, memory is comprised of two distinct systems with unique structural and functional properties. The first system consists of verbal representations and is based on language; the second derives from perceptual experience. Imagery can facilitate the recall of verbal material because the presentation of a word (e.g. apple) activates not only the linguistic memory trace, but also the visual memory related to the word. Consequently, concrete words are recalled more successfully than abstract ones because the former are more likely to activate a visual memory trace (Paivio, 1991). Numerous subsequent studies have shown that the concreteness of a piece of text is a key predictor of subsequent recall performance (e.g., Sadoski et al., 2000).

Reasoning and Mental Models

Mental imagery and reasoning are strongly interconnected (De Soto et al., 1965). Reasoning is a cognitive process in which new information is derived from statements provided to the participant. Two major theories have dominated the cognitive literature on deductive reasoning. The *mental logic theory* posits that the deductive processes are carried out by a system of linguistic rules sensitive to the logical form of the argument (Rips, 1994), whereas the *mental model theory* proposes that a visuo-spatial representation of the argument is constructed and evaluated (Johnson-Laird, 1994). According to the mental model theory, many problems can be solved in an analogical, 'pictorial' format: in fact, a mental model can be conceived as a representation *isomorphic* to the physical situation that it represents, and in which the inference simulates the physical processes being reasoned about. Imagery seems to be particularly important for *relational reasoning*, in which the problem is usually given by two statements (referred to as premises) and the task is to derive the conclusion that follows from these premises. A basic example of relational reasoning is 'If A is taller than B and B is taller than C, is C shorter than A?' A relational reasoning problem can be represented as a mental image where the conclusion can be 'read off' by inspecting the mental image (Goodwin and Johnson-Laird, 2005). According to this approach, the information given in the premise is integrated into a single spatial representation that usually takes the form of a linear array. This array is generally left-to-right oriented as a result of a cultural bias in visual scanning. As computational models suggest, the inspection process can be functionally described as a shift of spatial focus that checks the various cells of the spatial array and infers from the scan direction the relation between two objects in the array (Schlieder and Berendt, 1998). This type of representation can be used to derive novel conclusions even when the relation is temporal or abstract (Boroditsky, 2000; Goodwin and Johnson-Laird, 2005).

Although some studies have found positive effects of imageability on reasoning, others have failed to obtain such results. This discrepancy may result from the difference between *spatial imagery* and *visual imagery* (Knauff and May, 2006). *Visual imagery* refers to the representation of the visual appearance of an object, including its shape, color, and brightness, whereas *spatial imagery* refers to the representation of the spatial relationships between the parts of an object and the location and movement of the object in space. *Spatial* imagery has been proposed to be critical for reasoning while the generation of visual images can occur when the generation of the appropriate spatial mental model requires the retrieval of spatial information from a visual image (Knauff and May, 2006). In these situations, additional processes come into play, which can even impede the reasoning process (Knauff and Johnson-Laird, 2002). In short, the 'structure' of the reasoning process is likely to consist of spatially organized mental models that cannot be identified with visual images.

Mathematics and Numerical Cognition

It has been suggested that all mathematical tasks require *spatial* thinking. As in reasoning, the distinction between spatial and visual imagery is important (Hegarty and Kozhevnikov, 1999). The use of schematic images (i.e. images that encode the spatial relations described in a problem) has been found to be positively correlated with success in mathematical problem solving in sixth-grade students, whereas the use of pictorial images (i.e. images that encode the visual appearance of objects or people) have the opposite effect (Presmeg, 1997, 2006). Presmeg (2006) has identified five types of visual imagery that can be used by students to solve mathematical problems: (1) concrete pictorial imagery (pictures in the mind); (2) pattern imagery (pure relationships depicted in a visual-spatial scheme); (3) kinaesthetic imagery (hand movement and other gestures); (4) dynamic imagery (dynamic transformations of geometric figures); and (5) memory of formulas, wherein visualizers typically imagine a formula written on a blackboard or in their notebook. Only some forms of imagery facilitate performance and others may even be harmful (Presmeg, 1997, 2006). For instance, the use of concrete pictorial imagery may focus reasoning on irrelevant details that distract from the key elements of the problem. Pattern imagery (i.e., imagery where pure relationships are depicted in a visual-spatial scheme) may be the most useful type of imagery in mathematical reasoning because it represents the *relational* aspects of a problem and is better suited to abstraction and generalization (Presmeg, 1997, 2006). Data obtained with gifted students and with those affected by learning disabilities support this view. The former have been found to perform better in spatial visualization tasks than students with learning disabilities as well as average-performing students, and the use of schematic imagery in problem solving is positively correlated with performance on each spatial visualization measure (van Garderen, 2006).

Creative Thought

Mental imagery is known to have played an important role in the work of many great scientists, for example, in Galvani's discovery of 'animal electricity' (i.e. the electricity present in

a condition of disequilibrium between the interior and the exterior of excitable animal fibers) (Piccolino, 2008). However, most of the available positive evidence is based on self-reports of major figures in the history of science rather than on empirical studies. According to a meta-analysis by LeBoutillier and Marks (LeBoutillier and Marks, 2003), imaging capacity may account for only the 3% of the total variance in divergent thinking (i.e., creative thought) measures. Mental imagery has been widely investigated in psychology of sport, where its use has been demonstrated to be beneficial to improve athletes' performances (see Smith and Wright, 2008) and in the training of high-level manual skills. For example, imagery is frequently used by surgeons as preparation for operations (Sanders et al., 2008).

Imagery and Perception: Where in the Brain?

Neuroimaging techniques (such as positron emission tomography (PET), functional magnetic resonance imaging (fMRI)) and noninvasive brain stimulation techniques (such as transcranial magnetic stimulation (TMS)) have been instrumental in our understanding of cortical circuits involved in visual imagery. Several neuroimaging studies have found visual imagery to engage the primary visual cortex and extrastriate cortices (for reviews, see Kosslyn et al., 2001; Kosslyn and Thompson, 2003) and imagery vividness appears to be positively correlated with visual cortical activity (Cui et al., 2007). Using brain stimulation, it is possible to transiently impair the activity in specific brain areas and assess their causal role in cognitive tasks. Application of TMS over the primary visual cortex has been found to impair performance in visual imagery, demonstrating that activity in this region is functionally significant for visual imagery, rather than merely being epiphenomenal (Cattaneo et al., 2009). Furthermore, visual cortex excitability is increased by visual imagery, demonstrating that the engagement of imagery recruits the early visual cortex (Sparing et al., 2002; Cattaneo et al., 2011). A particularly direct demonstration of the overlap between visual perception and imagery comes from a study by Kreiman et al. (2000), in which neural activity was directly recorded from patients undergoing surgery. It was found that many of the same neurons were activated by visual presentation of stimuli as well as when the participants were asked to imagine these visual stimuli. This is, perhaps, the strongest single piece of evidence indicating an overlap between the neuronal basis of visual perception and imagery.

Further evidence has come from the use of the fMRI-adaptation paradigm, which is based on the reduction of the BOLD signal when a sensory stimulus is repeatedly presented. Yi et al. (2008) found that the effect of mentally visualizing a recent perceptual stimulus was comparable to its repeated visual presentation, suggesting that the same population of neurons in the visual cortex is involved in visual perception and mental imagery. Furthermore, category-specific visual areas were activated when participants imagined faces, houses, or chairs; thus the extrastriate processing of imagery is associated with similar functional specialization as visual perception (Cichy et al., 2012; Ishai et al., 2000; O'Craven and Kanwisher, 2000). Similarly, Goebel et al. (1998) found activity in perceptual motion area V5/MT when participants were required to imagine movements. Furthermore, the spatial extent of imagined objects has been found to match with the known spatial organization of early visual areas, with objects subtending smaller visual angles producing activity near the occipital pole (where stimuli falling in the central visual field are represented), and objects subtending larger visual angles inducing more anterior activity (where stimuli falling in the peripheral visual field are represented) (Kosslyn et al., 1995). Finally, behavioral cross-adaptation effects between imagery and visual perception have been observed in conjunction with brain stimulation, which have provided direct causal evidence for the recruitment of the same orientation channels in the early visual cortex (V1/V2) in both imagery and perception (Cattaneo et al., 2012).

According to Kosslyn (1994; Kosslyn et al., 2006), the overlap in cortical regions involved in imagery and perception reflects the involvement of the visual buffer in both processes. In Kosslyn's view, visual mental images arise through reactivation of the same cortical areas that process the relevant information during perception. Such reactivation mechanism of visual cortices would be possible by means of top-down projections from other (higher-level) cortical areas. Whether visual imagery involves primary visual cortices (V1) has been a controversial issue. Slotnick et al. (2005) reported that a high-resolution visual mental imagery task evoked topographically organized activity in striate cortex, but this was found only in half of the participants. Furthermore, V1 activity in imagery may reflect memory processes rather than imagery per se. Kaas et al. (2010) used a motion imagery paradigm in which participants were never presented with a stimulus identical to the one they had to imagine. The authors found increased activation in the motion-selective extrastriate area hMT+/V5, whereas critically, the BOLD signal in V1 was *decreased* during imagery – a result in accordance with the view that conscious visual perception is suppressed during mental imagery. Because in most imagery studies participants are instructed to imagine a manipulated version of a stimulus they have encountered during the experiment, the observed V1 activation might reflect memory for the stimulus on which visual imagery is based rather than the mental image per se. According to a meta-analysis of imagery studies carried out by Kosslyn and Thompson (2003), two variables predict whether early visual areas are activated during visual mental imagery: firstly, the imagery task needs to involve high-resolution images (with details subtending 1 degree of visual angle, or less) and secondly the task should not rely on the processing of purely spatial relations. The overlap of cortical networks involved in perception and imagery is not complete, however, as shown by neuropsychological evidence. For example, there are reports of patients with severely impoverished imagery abilities despite normal visual perception and an anatomically intact primary visual cortex (V1; Moro et al., 2008). However, traumatic brain injuries like those suffered by patients mentioned by Moro et al. (2008), typically involve diffuse axonal injury, which are likely to disrupt large-scale brain networks that are involved in imagery processes beyond early visual cortices.

Neuropsychological studies have found dissociations between spatial and visual imagery (Farah et al., 1988); for example, patients may be severely impaired in tasks assessing visual imagery while displaying normal performance for spatial imagery. Accordingly, it has been suggested that mental imagery is subject to the same dichotomy that characterizes visual perception, namely a distinction between a dorsal pathway specialized in the processing of spatial attributes and a ventral pathway focused on shape and color (Mellet et al., 1996). In line with this, purely spatial mental imagery tasks have been found to activate regions along the dorsal pathway but not early visual cortices (Mellet et al., 1996). For example, the clock task that requires the forming of a mental image depicting the spatial relationship between clock hands from verbal instructions (see the next section for further details on this task), strongly activates the intraparietal sulcus (IPS), a region along the dorsal route generally recruited during execution of visuospatial perceptual tasks (Trojano et al., 2000). A meta-analysis of 32 neuroimaging studies found that mental rotation is usually accompanied by increased activity in the IPS and adjacent regions, and that the amount of activation in these regions is consistently reflected to the amount of mental rotation required by each specific task (Zacks, 2008).

Finally, although most of the neuroimaging studies have been carried out on visual imagery, partially overlapping networks for perception and imagery have also been reported for tactile, auditory, olfactory, gustatory, and motor imagery (Kobayashi et al., 2004; Stevenson and Case, 2005).

Measuring Imagery Abilities in Health and Disease

A number of paradigms have been developed to measure imagery (for a review, see Pearson et al., 2013). Among the tests developed to test image generation ability, some require generation of a matrix of a given size (e.g., 4 × 5 and 5 × 5, depending on the specific version of the task) in which some squares are shaded, forming random patterns (Podgorny and Shepard, 1978) or a letter (Kosslyn et al., 1988). In these paradigms, the behavioral task assessing imagery accuracy involves judging whether a probe item falls within the generated pattern. In a similar paradigm, participants are asked to memorize a series of randomly positioned dots and, after a retention interval, an arrow is presented; participants are then required to report whether the arrow points to one of the originally presented dots (Finke and Pinker, 1983). Another common test of imagery generation is the clock test, originally developed by Paivio (1978) and used in many variants (Grossi et al., 1989; Cattaneo et al., 2009). In this task, individuals have to convert a digital time (e.g., '2:45') into the corresponding analog image and to compare angles (formed by the clock hands) corresponding to different digital times. In order to perform the task successfully the observer needs first to generate the image of the clock hands corresponding to each of the two given times. Both images then need to be held in WM in order to allow a direct comparison between the two angles. Among the tasks used to assess image maintenance, the visual pattern test developed by Della Sala et al. (1999) requires observers to memorize a pattern of cells visually presented on a matrix and then reproduce them on a blank matrix after some retention interval.

Cocude and Denis (1988) also developed a test to measure *imagery duration*. In their task, participants were asked to generate mental images in response to given words varying in degree of concreteness and then to indicate when their imagery experience of the images ceased. *Image inspection* has been investigated in map scanning tasks (e.g., Mellet et al., 2002), already described earlier in this article (see **Figure 1**), requiring participants to mentally move from one location on the map to another.

Mental size comparisons tasks have been widely used to measure image inspection capacity. In these tasks, participants are asked to report, for example, which of two animals is the larger (Moyer and Bayer, 1976). To perform successfully in these tasks, participants need to form a mental image of both animals and to compare them visually. *Image transformation and manipulation* can be assessed using the mental rotation task originally developed by Shepard and Metzler (1971) and described earlier in this article (see **Figure 1**). Some tasks have been specifically designed to tap the capacity to create a new image (mental synthesis): for instance, Finke et al. (1989) required participants to follow instructions such as, "Imagine a capital letter D, rotate it by 90 degrees to the left. Now place a capital letter J at the bottom. Identify the final figure (an umbrella)".

Other tests have been used to assess how mental imagery is subjectively experienced. The phenomenological characteristics of mental imagery have been studied with subjective measures in which individuals are asked to describe and rate a mental image in terms of vividness (Pearson et al., 2001; Bona et al., 2013). Betts' Questionnaire upon Mental Imagery (Betts, 1909) and the Vividness of Mental Imagery (VVIQ, Marks, 1973) are examples of such tests. Both require participants to rate the vividness of mental images generated on the basis of verbal instructions. Tests have also been developed to investigate how often individuals spontaneously use imagery (Spontaneous Use of Imagery Scale, SUIS; Reisberg et al., 2003), in thinking and episodic memory (Holmes et al., 2008) or in problem solving (the Visualiser-Verbaliser Cognitive Style Questionnaire, Kozhevnikov et al., 2005).

Conclusions

Mental imagery refers to internally generated conscious experiences, perceived in the 'mind's eye,' which can be generated from items in LTM or STM. Its importance was recognized already by the philosophers of Ancient Greece, who argued that 'the soul never thinks without a mental image.' Imagery is an important cognitive structure also because it contributes to other cognitive processes such as memory, reasoning, and creativity. Particularly, in the memory literature there is much evidence of the beneficial contribution of imagery to recall performance. From a theoretical perspective, imagery has been the subject of much controversy. The so-called 'imagery debate' has centered on two competing theoretical viewpoints, the *pictorial* (or *depictivist*) *theory* and the *propositional* (or *description*) *theory*, and it has been perhaps the most hotly debated topic in the study of visual imagery. Over the past

two decades, neuroimaging and brain stimulation techniques have begun to shed light on the brain basis of imagery processes. These studies have revealed the involvement of the same brain regions that encode incoming sensory information, indicating that imagery from the neural perspective is sensory in nature.

Abstract

Attitudes and behavior toward those with mental illness and those who deal with mental illness are important to study for a number of reasons. These reasons include engagement with services but also research and service funding. Numerous studies have shown high prevalence of negative attitudes among the general public toward people with mental illness, such as beliefs that people with mental illness are dangerous, lack will power, and are unreliable. Attitudes can be assessed individually; but, attitudes often reflect cultural context and in turn are influenced by a number of other factors. The formation of attitudes can be related to upbringing, past experience, knowledge, and other variables. Although attitudes do not always turn into behavior, public attitudes can have significant consequences for people with mental illness including higher rates of mortality, higher levels of self-stigma, lower levels of empowerment, lower levels of help-seeking, and higher rates of unemployment (S. Evans-Lacko et al., 2012; Hatzenbuehler et al., 2013; Rüsch et al., 2005; Schomerus et al., 2014). Awareness of attitudes and beliefs among the public is germane for developing primary prevention programs, early intervention, and community-based treatments.

Public attitudes toward mental illness and people with mental illness more generally vary according to a number of internal factors such as personal experiences and/or contact with people with mental illness and external factors including the media, cultural beliefs, and legislation. Attitudes differ according to age, gender, socioeconomic status, and cultures. It can be argued that it is not the illnesses per se that provoke negative attitudes, but what they represent (i.e., 'the outsiderness') that may be seen as frightening and that may increase social distance. These attitudes may or may not always translate into behavior, but can influence the allocation of resources into the delivery of mental health services (P.W. Corrigan and Watson, 2003), recruitment into various branches of mental health professions (Mukherjee et al., 2013), and general acceptance of people with mental illness by the larger community (Hatzenbuehler et al., 2013).

Definitions

Mental illness is a broad generic term that includes major mental illnesses such as schizophrenia, bipolar affective disorders, common mental disorders such as anxiety and depression, personality disorders, and various other conditions sometimes named after etiology (for example, posttraumatic stress disorder) or after behaviors (e.g., episodic dyscontrol syndrome). Therefore, when discussing attitudes toward mental illness, it is important to keep this context in mind as different conditions may be associated with different attitudes. For instance, a national sample of British adults showed that more than 70% of the public thought people with schizophrenia were a danger to others; however, less than 10% felt that people with eating disorders were dangerous (CRISP, 2000). The public also differs in terms of how they classify and conceptualize mental illnesses and this can influence their attitudes toward people with mental illness too. One study identified a two-factor model of views of mental illness with one group identifying only major psychiatric disorders (e.g., schizophrenia and bipolar disorder) to be mental illnesses and the other group identifying drug addiction and external stressors as a mental illness, suggesting a broader and less specific concept of mental illness (Rüsch et al., 2012). These types of classifications of types of mental illness are related to attitudes toward people with mental illness and toward help-seeking. For instance, identifying major psychiatric disorders as mental illness is associated with more positive attitudes toward people with mental illness and a greater likelihood of help-seeking, though the broader perspective is associated with greater comfort in disclosing a mental health problem (Jorm et al., 2006b; Rüsch et al., 2012; Wright et al., 2012). Because of negative associations identified with various mental illness conditions and how they are named and/or classified, it has been suggested that changing the names of conditions and using terms which more clearly reflect recovery could be important for reducing stigma; but, it seems that the process is complex and the context which shapes attitudes and stigma is more important. Thus research which is available suggests that renaming in and of itself will not change stigma (Patrick W. Corrigan, n.d.).

Attitudes

Attitudes form a key point of an individual's thinking, especially toward things that matter to the individual. Attitudes have several components – some a function of the dimensions of personality traits, whereas others are a function of experience. Assessing attitudes provides a window into belief systems, but these do not always translate into behavior. Both cognitive and affective components of attitudes should be assessed, separately and together. Attitudes do not always remain static and are influenced markedly by a number of factors such as media, education, and societal conditions.

Stigma

Stigma is the expectation of stereotypical and discrediting judgment of oneself by others in a particular context. The term

originates from Goffman's (1963) definition of stigma, which states that stigma originates when an individual, because of some attributes, is disqualified from full social acceptance. Stigma, like the attributes, is deeply embedded in the sociocultural milieu in which it originates and is thus negotiable.

The Greeks in ancient times used the word 'stigma' to refer to bodily signs that exposed something unusual and negative about the signifier. Further conceptualization of stigma has included a mark that sets an individual apart (by virtue of mental illness in this case), that links that individual to some undesirable characteristic (perceived or real in cases of mental illness using violence, fear, and aggression) and rejection, isolation, or discrimination against the individual (e.g., at the workplace by virtue of the sick role and mental illness). Stigma thus includes cognitive and behavioral components and can be applied to age, race, sexual orientation, criminal behavior, and substance misuse, as well as to mental illness. The label and negative stereotypes are then extended to all those who have the characteristic. Social exclusion may be seen as necessary for bifurcation of society and will take the same role as scapegoating. Stigma and negative attitudes to mental illness are by and large universal. These are briefly discussed below to highlight similarities prior to discussing various factors responsible for these attitudes.

Attitudes in Europe

Negative attitudes toward people with mental illness are represented by the public and professionals in all countries and cultures and can be considered global phenomena (S. Evans-Lacko et al., 2012; Lasalvia et al., 2012; Schomerus et al., 2014; G. Thornicroft et al., 2009), however, variation in attitudes and beliefs are represented even within different countries of Europe. In this section some of the key studies and the findings are reported.

Historical

In ancient Greece, stigma and shame were interlinked and these can be studied using theories of causation and the balance within the culture between exclusion of individuals with mental illness and the ritual means of cleansing and re-inclusion. The interwoven theories of shame and stigma suggest that, in spite of scientific and religious explanations, attitudes were generally negative. Simon (1992) suggests that the ambivalence of the ancient Greeks can explain their attitudes toward mental illness. The diseases of the mind were seen in parallel with those of the body, and even the doctors were part and parcel of the same cultural ambience of competition, shame, and fear of failure. During the Medieval and Renaissance periods, mental illness was perceived as a result of imbalance of various humors of the body, and related concepts of shame contributed to this. As Christianity encouraged a God-fearing attitude to the world, mental illness was seen as a sign that God was displeased and punishing the individual, thereby making negative attitudes more likely and more acceptable.

In the seventeenth and eighteenth centuries the context shifted; but, overall remained negative and in turn provided entertainment to the visitors to the Bedlam asylum where individual visitors paid a penny to see the inmates. In the nineteenth century, with the establishment of various psychiatric asylums, there was generally a growing perception among the lay public and physicians alike that the mind is a function of the brain, thereby influencing a shift toward more humane treatments – although these were still called moral therapy, thereby giving it a moral/religious tinge. The Athenian thinking on psyche has influenced these attitudes. Porter (1987) proposed that the growing importance of science and technology (among other things) was influential in channeling the power of right-thinking people in imposing the social norms. The men of the church (also men of power) influenced public opinion, and informed attitudes and behavior toward marginal social elements that would then become disturbed and alien. Central state or market economy influenced the expectations which then divided those who set and met the norms from those who did not.

Modern Context

In a survey from 1957, the British Broadcasting Corporation (BBC, 1957) reported that the public's tolerance of individuals with mental illness depended upon the circumstances in which contact was made. More than three-quarters of those surveyed were willing to mix with individuals with mental illness in areas where low personal involvement occurred; only half were willing to work with people with mental illness, whereas only a quarter were agreeable to such an individual being in authority over them.

As mentioned previously, attitudes toward mental illness are influenced by a number of external factors such as sociopolitical context, expectations of treatment, etc. In Greece, one study showed that individuals who were younger, more educated, and of higher social class saw mental illness as a psychosocial problem, whereas older people saw it as a disorder of the nervous system (Lyketsos et al., 1985). Brändli (1999) observed that in Switzerland stigma was more common in older nonurban males with low education and low mental health literacy. The findings also suggested that the general public was more accepting of seeking help from their primary care physician compared to a psychiatrist. Indeed, several more recent studies have identified a link between stigma and intended (Angermeyer et al., 2013; Mojtabai, 2010; Rüsch et al., 2011; Ten Have et al., 2010) and actual help-seeking (S. Evans-Lacko et al., 2012a) across several European countries. Research from Germany suggests that in recent decades, the general public is much more likely to recommend help-seeking from mental health professionals; however, social distance in relation to people with mental illness has not decreased (Angermeyer et al., 2013).

Across Europe, there have also been comparative studies and research that pools and compares attitudes across European countries. Studies using the Eurobarometer data, including nationally representative samples across 27 EU countries, show that negative attitudes at the country level are associated with lower levels of help-seeking (Mojtabai, 2010), higher rates of suicide (Schomerus et al., 2014), and higher rates of unemployment for people with mental health problems (S. Evans-Lacko et al., 2013). For instance, we know that people with mental illness have higher rates of unemployment compared

to those without mental illness. One recent study showed that individuals with mental health problems living in countries with higher levels of stigmatizing attitudes regarding dangerousness of people with mental illness were more vulnerable to unemployment, particularly during the macroeconomic recession, in 2010 (S. Evans-Lacko et al., 2013b).

A recent systematic mapping of the literature that reviewed studies across Europe between 2007 and 2012 demonstrated a growing interest in stigma and social inclusion research via increased publications. Most studies included in the review were based in Northwest Europe (especially in the UK, Finland, Sweden, and Germany). Research tended to be more descriptive rather than focusing on mechanisms or interventions that could improve attitudes, and this is a gap that should be addressed in future research (Sara Evans-Lacko et al., 2014). There is some work that looks at the effectiveness of anti-stigma interventions for improving attitudes. More recent research from the UK has demonstrated improvements in attitudes toward people with mental illness; however, these occurred alongside concerted anti-stigma efforts. More positive attitudes in relation to prejudice and exclusion were particularly notes and these may be due to the effectiveness of the national Time to Change anti-stigma campaign (S. Evans-Lacko et al., 2013a,b; Evans-Lacko et al., 2014a,b).

The attitudes of other medical and nonmedical professionals are also important, but are beyond the scope of this chapter.

Attitudes in North America

In North America, there are a number of studies related to stigma carried out by medical and social scientists that have illustrated a range of attitudes to a number of conditions. Here only a subset of these studies will be discussed.

Historical

In America from the seventeenth century onward, the traditional belief prevailed among Christians that madness is often a punishment delivered by God on the sinner, and this influenced subsequent views and attitudes. Although both physical and mental illnesses were seen as punishments, it was only in the latter that moral components were seen, especially in the context of teachings from the Bible. A lack of faith and persistence of sinful and lewd thoughts were seen as key causation factors in the development of insanity.

In the early 1940s, Cumming and Cumming (1957), in their classic study of lay public perceptions of people with mental illness, showed significant rejection of people with mental illness. They performed one of the earliest educational interventions in a small community in Canada, aiming to improve stigmatizing attitudes; however, these attempts were unsuccessful and it is reported that attitudes became even more hostile.

In the 1940s, Ramsey and Seipp (1948) demonstrated that subjects who had higher socioeconomic and educational levels were less likely to view mental illness as a punishment for sins and/or poor living conditions. Yet they were less pessimistic about recovery.

Modern Context

Vignettes have been used to determine public knowledge of mental illness, and public attitudes toward people with mental illness for several decades (Star, 1952). Crocetti and Lemkau (1963) used vignettes to demonstrate that virtually all the subjects in their sample agreed with the question, 'Do you think that people who are mentally ill require a doctor's care as people who have any other sort of illness do?' In this sample, low social class and low educational levels were not associated with negative attitudes. In another study using case vignettes, it was shown that the largest increase in rejection rates occurred when a person had been admitted to a mental hospital and this was seen as due not to the fact that they were unable to help themselves, but that a psychiatrist or mental health professional had confirmed their status as 'mentally ill' (Phillips, 1963). The rejection appeared to be based on how visibly the behavior deviates from the customary role expectations. Continuance of symptoms, and public visibility of these symptoms, and behavior, influences attitudes and makes them more negative.

Social distance measures assess the degree to which individuals avoid or disassociate themselves with people with mental illness. Assessments have examined a number of parameters, especially in social interactions, but also the likelihood that individuals would employ or rent to people with mental illness (P.W. Corrigan, 2001; Link and Phelan, 2001). Additional research has shown that individuals may be willing to accept individuals with mental illness in certain contexts, but reluctant to interact with them in social situations. Dovidio et al. (1985) examined first impressions among undergraduate students of individuals with mental illness in the process of college applications. The results suggested that individuals with mental illness were seen favorably in terms of character and competence, but negatively in the context of security and sociability.

An important factor related to social distance is personal contact with people with mental illness. Analysis of a nationally representative survey of individuals in the USA showed that those who reported previous contact (defined here as a history of psychiatric hospitalization among the respondents themselves, their family, or their friends). In this study, previous contact was associated with 'having a less ostracizing, critical attitude toward a stranger with mental illness' (Boyd et al., 2010). Indeed a recent meta-analysis of studies looking at effects of anti-stigma approaches identified contact, particularly face-to-face contact, as having positive effects for reducing stigma (Patrick W. Corrigan et al., 2012).

Newer research suggests that we need to look specifically at types of stigmatizing attitudes and their relation to consequences, as different types of stigma may vary in their impact. For instance, recent research has shown that a belief that people with mental illness are dangerous is associated with greater likelihood of help-seeking, more support for coercive treatment (P. Corrigan et al., 2003; Mossakowski et al., 2011), and a biogenetic explanation for mental illness (Kvaale et al., 2013). It may be that a 'medicalized' concept of mental illness in which mental illness is considered 'a disease like any other,' (Pescosolido et al., 2010) is associated with greater help-seeking, but also more social distance.

Attitudes Elsewhere in the World

Although the majority of attitude studies have been performed in North America, Western Europe, and Australia, there are a growing number of studies carried out elsewhere.

Historical

In ancient Ayurvedic texts, the description of mental illness also suggested physical forms of treatment. Diet and seasons were reported as playing key roles in the genesis of such conditions. This approach allowed the locus of control to be shifted to some degree away from the individual, thereby making that individual less responsible and less likely to be stigmatized.

Current

Ilechukwu (1988), in a survey of 50 male and 50 female psychiatric outpatients in Lagos, demonstrated that some patients did believe in supernatural causes of neuroses and disorders, but psychosocial causes were cited most commonly. The attitudes and beliefs of patients are important, but are beyond the scope of this article.

Wig et al. (1980), in a three-site study from India, Sudan, and the Philippines, found that, when asked to comment on case vignettes, community leaders were able to identify mental retardation (in all sites), alcohol and drug-related problems (in the Sudanese and Philippines areas), and acute psychosis (in India). Thus it appears that there are differences in the identification of different clinical conditions. They also reported that attitudes toward people with mental illness were more negative in India compared with the other two sites. There has also been some investigation of stigma in relation to religion. Verghese and Beig (1974), in a survey from South India, reported that over 40% of Muslim and Christian respondents reported that marriage can help mental illness, although only 20% of Hindus shared this belief. Virtually no respondents reported believing in evil spirits. The most commonly recognized causes mentioned were emotional factors, including excessive thinking. In respondents over the age of 40, one-fifth saw mental illness as God's punishment. Christians were again more likely than Hindus to fear people with mental illness (although this fear diminished with higher levels of education), and yet Christians were more likely to believe strongly in the possibility of recovery. Nearly three-quarters of Hindus believed that the moon influences mental illness. These are interesting findings in that they address religious differences in public attitudes.

The number of studies in other parts of the world is likely growing. Previously, a gap was noted in terms of understanding stigmatizing attitudes and beliefs about mental illness in Africa, but there are now several studies that have been recently published (Barke et al., 2011; Crabb et al., 2012; Wakil et al., 2013). A recent review of mental health-related stigma in Japan identified 19 studies. Many of the conclusions in terms of what types of factors are associated with less stigma (e.g., personal contact) were similar to those found in other countries; for example, it is common to find that schizophrenia is associated with more stigma than depression. Studies did suggest, however, higher levels of stigma in Japan compared to Australia and Taiwan (Ando et al., 2013). A number of attitude studies and anti-stigma interventions have been performed in Australia, particularly in relation to evaluating the Beyond Blue anti-stigma campaign (Jorm et al., 2006a; Jorm et al., 2006b; Yap et al., 2012).

Characteristics Associated with Negative Attitudes

Reactions to a taboo or outsider group depend upon a number of factors. These include the frequency of the actual or anticipated behavioral events, intensity and visibility of such behavior, and circumstances and location of such behavior on the one hand, and personal factors on the other. In this section we focus on the latter.

Age

Several studies have shown that older people tend to have more negative attitudes toward people with mental illness. The reasons for this are many. Older people, in spite of their life experiences, are generally more conservative and equally rejecting of behavior which is seen as odd and alien. The role of age is likely to be mediated by other factors such as education, social and economic class, etc.

Types of Illness

As discussed previously, attitudes toward people with schizophrenia are likely to differ from those reported toward people with depression or personality disorder. This may reflect the stereotypic images of the condition or fear related to the condition. It may also be due to previous knowledge about the illness. The perceived causative/etiological factors also play a role in attitudes.

Gender

Males tend to have more negative attitudes and, as noted above, are also more likely to be rejected when they have a mental illness; females may be more sympathetic. Other studies of attitudes toward other minority groups also demonstrate that females are more positive. They are also more likely to be carers, and may be the first to contact psychiatric services on behalf of individuals. For women, a change in role after developing mental illness is likely to be associated with more stigma than is the case in men. Yet they are more likely to be admitted with more 'masculine' illnesses such as personality disorder and drug abuse. The gender roles in the context of illness may well play a role in generating negative attitudes.

Religious Beliefs

Some studies have demonstrated that Christians tend to have more negative attitudes toward mental illness, but again this is not a consistent finding. The individual subject's level of religiosity and depth of religious values must be studied rather than simple religious ascription.

Educational Status

The effects of education on attitudes are mixed. Some studies have identified negative attitudes to be associated with low educational status, whereas others have failed to show such association, or showed that highly educated subjects held more negative attitudes, including those with professional qualifications.

Professions

Medical students may hold more negative and stereotypical attitudes, and other branches of medicine too have been shown to have negative attitudes toward people with mental illness and psychiatry as a profession. The psychiatrist is often lampooned and seen as a 'head shrinker' or a modern-day witch doctor. There are individuals who are well educated and belong to a high socioeconomic class and yet hold negative attitudes.

Others

Some ethnic groups such as African-Caribbeans in the UK and Hispanics, Asian-Americans, and Mexican-Americans in the USA have been found to have more negative attitudes toward people with mental illness or be more restrictive in their description of etiology of mental illness compared to the white majority population. Non-acculturated individuals appear to have more negative stereotypes about people with mental illness compared to those who are considered to be acculturated.

These are some of the complex set of factors that influence attitudes and stereotypes.

Interventions

There are three main strategies for improving stigmatizing attitudes toward people with mental illness described in the literature: protest, education, and contact (P.W. Corrigan et al., 2001). Protest aims to eliminate negative stereotypes in public statements, media reports, or advertisements (Rüsch et al., 2005). Education provides evidence-based information about mental illness or demonstrates how negative attitudes are represented in society, and what the consequences of this might be. The third strategy involves direct contact with people with a psychiatric disorder and it has been recognized as one of the most effective ways to fight stigma and discrimination (P W Corrigan et al., 2012; Sara Evans-Lacko et al., 2012b). Social contact is associated with a reduction in anxiety and also provides an opportunity to check '*in vivo*' the invalidity of one's own prejudices (S. Evans-Lacko et al., 2012b). Although contact has the strongest level of evidence, multifaceted strategies are encouraged and it is important to target anti-stigma work based on the type we seek to eradicate.

Wolff et al. (1999) reported on the results of follow-up of neighbors, where two group homes for people with mental illness had been set up and one set of neighbors had received extensive education. They found that although the public education intervention may have had at best only a modest effect on knowledge, behavior toward the residents with mental illness changed. There was a decrease in fear and exclusion, and increased levels of social contact in the experimental area. They observed that educational intervention per se did not in itself lead directly to a reduction in fearful attitudes, whereas contact with patients did. Thus, any campaign that encourages subjects to increase contact with people with mental illness may prove to be more successful. The educational programs must be paced slowly and in a sustainable manner. The patients and their carers must be involved in planning these interventions without turning the whole exercise into a circus.

Anti-stigma interventions aimed at improving attitudes may, in the long run, influence resource allocation into mental health, improve recruitment, and move toward acceptance of community care. These interventions are also important to consider as they may reduce fear and prevent attitudes from hardening. However, these interventions must be clear, focused, and appropriate, based upon the needs of the group that is being educated rather than on perceptions of need by the professionals. Corrigan has identified five principles for strategic stigma change: consumer contact that is targeted, local, credible, and continuous (Patrick W. Corrigan, 2011). Several large-scale evaluations have now been published (Dunion and Gordon, 2005; S. Evans-Lacko et al., 2010; S. Evans-Lacko et al., 2013; Svensson and Hansson, 2014; C. Thornicroft et al., 2014); however, further evaluation of anti-stigma programs is required to better understand the key factors, mechanisms, and pathways to improve attitudes in a sustained way.

Conclusions

The attitudes of the public toward individuals with mental illness reflect prevalent social norms and mores. Expectations from psychiatric services, response to treatment, type of treatment, type of mental illness, and inaccessibility to treatment are external factors that will influence public attitudes. Age, gender, personality traits, and social and economic class are associated with different attitudes. These attitudes will not always translate into behavior, but are interrelated and have significant consequences for people with mental illness, leading to exclusion and disadvantage, for example, through reduced participation in higher education, exclusion from civil society (including functions such as democratic participation), increased risk of contact with criminal justice systems, victimization, less access to physical health care, poverty and homelessness, and reduced life expectancy. As we further our understanding of the mechanisms that facilitate and maintain negative stigmatizing attitudes through more robust evaluation, we also need to further develop and refine our anti-stigma strategies.

Mentoring: Supervision of Young Researchers

Rachelle Hollander, National Academy of Engineering, Washington, DC, USA

© 2015 Elsevier Ltd. All rights reserved.

Abstract

More and tighter coupling between academic and other social institutions has prompted increased attention to ethical aspects of the relationships between established researchers and researchers-in-training, including graduate students and new researchers in the United States and other countries. Questions about the responsibilities of individual and institutional parties to these relationships arise, and persons and institutions try to respond. This article reviews recent guidance that scholars and professional groups have developed, particularly in the United States, and ends with suggestions for departments and institutions that can help them fulfill requirements for appropriate mentoring and supervision.

Context

The US National Science Foundation *Science and Engineering Indicators 2012* (*SEI 2012*) reports that US institutions granting doctoral degrees awarded 41 100 in fields of science (including psychology and social sciences) and engineering in 2009. Foreign students earned 57% of all engineering doctorates, 54% of all computer science degrees, and 51% of physics doctoral degrees. Their overall share of S&E degrees was one-third. *SEI 2012* also reports that in sum about 194 000 S&E doctoral degrees were earned worldwide in 2008. In 2007, China overtook the United States as the world leader in the number of doctoral degrees awarded in the natural sciences and engineering. Standing at the peak of a large educational enterprise which represents a large social investment, these numbers indicate the large-scale context in which post-baccalaureate education operates (National Science Board, 2012).

Given the scale of these investments and the importance for society of results from research activities using graduate and postdoctoral assistance, it is not surprising that questions arise concerning the roles and responsibilities of graduate students, postdoctoral associates, faculty, and their institutions. The system shows the strains of increasing numbers as well as mounting calls for accountability from graduate students themselves and the governmental funders and sponsors of graduate education. In the United States, graduate students have begun to organize and gain collective bargaining rights on campuses and postdoctoral associates are pushing for national reforms to their status, including written contracts, uniform job titles and benefits, support for postdoctoral associations, representation on institutional policy-making committees, and a national postdoctoral organization.

In the past decade national and international councils have begun to address issues of ethics and mentoring in graduate education and associated research activities (InterAcademy Council, 2012). Adequate response to these stresses requires the attention of academic institutions and professional associations. Most important, perhaps, are the responses at the level of departments and programs actually producing new Ph.D.s. The beginnings of change can be seen in the developments described below; but better understanding of changes in mentoring practice and supervision requires systematic research attention, of a kind they still have not received, in order to identify and assess effects on individuals, departments, programs, and institutions, and to make improvements in the future.

Increased social and governmental attention to questions of research misconduct has given particular impetus for change in this arena. These concerns resulted in regulations in the US requiring institutions to establish procedures in response to allegations, and many other nations have implemented such procedures. Governmental and academic institutions, as well as scientific and professional associations, regard this as a broader mandate for education in research integrity. The US National Institutes of Health has established requirements for ethics training for all research staff, which have implications for mentoring and supervision.

The US National Science Foundation has issued requirements for mentoring postdoctoral fellows supported with its funds, and for ethics training for graduate students and postdocs.

Professional associations have been custodians of good practice for their members, as well as for practitioners and researchers who may not be members but draw on the body of knowledge that these associations incorporate and represent themselves as having the relevant expertise. Today's world requires that experts work with others with very different specialties more often than in the past; the need for these group or team efforts raises additional issues for good mentoring and supervision and for the effective review of research results.

Supervision

The US Council of Graduate Schools issued guidance for supervisory practice in 1990 (Council of Graduate Schools, 1990) and has followed up with the Project on Scholarly Integrity that published *Research and Scholarly Integrity in Graduate Education: A Comprehensive Approach* (Kent et al., 2012). The 2012 publication articulated a strong rationale for the need for institutions to layer their response to enhancing scholarly integrity by establishing efforts throughout the institutional hierarchy. The earlier guidance indicated that there are no recipes for the creative impetuses that underlie the most successful interactions between faculty members and students,

and provided useful recommendations to assist departments, programs, and supervisors to enable their students to make good progress. These recommendations are appropriate and can be adapted easily for use with postdoctoral fellows.

The guidance indicates that departments should have a clear written framework outlining the stages students are expected to complete in graduate training. Supervisors should help their students plan their time carefully, meet with them regularly, and be ready, at an early stage in the program, to make an assessment, which will be perceived to be fair and appropriate, about whether they should continue toward the Ph.D. Supervisors should engage the students early in research activities, in order to promote knowledge about the field and facilitate the selection of a dissertation topic. In research endeavors for graduate students, students should be discouraged from achieving perfect results at the expense of good research and should not be allowed to become distracted by interesting, but tangential, issues.

In readying students to undertake research, the department or program should clarify the standards it expects students to meet. Will a literature survey be necessary? Will experimental research or fieldwork be required? Are there certain techniques or tools that the student must master in the training program or dissertation? What writing standards must reports and theses meet? In the middle stages of training, graduate students should expect to complete most of the original work that will form the dissertation. Since research may lead in unexpected directions, supervisors and students need to be alert to considerations that might require modifying the original goals, particularly to allow completion of the project in a timely fashion. Careful records need to be kept, and here supervisory assistance and monitoring is most important and lays the foundations for good research practice throughout a career.

Team research may require additional considerations. There needs to be a careful definition of students' contribution to research work and the students should be given opportunities to demonstrate a broad understanding of project purposes and methods. Of course, students in individual projects also need opportunities for presentation about their status and findings. Writing should begin early in the project. Milestones here are useful. An introduction or overview as well as a list of references can be drafted and revised as work progresses. Questions about interim findings and the relation of the research to the work of others need to be posed so that students can stay abreast of developments in their fields. Experience demonstrates that students should be allowed to complete their dissertations before being asked to continue as a postdoctoral research associate.

Checklist for Supervisors and Departments

Does the department have a document describing its views on good supervisory practice? What steps exist to make good matches between supervisors and prospective students or postdoctoral associates? Should students and postdoctoral associates present reports for assessment by nonsupervisors early in their tenure? Do they make public presentations satisfactorily? Do they participate in developing proposals for research support? Are adequate meetings scheduled between supervisors and students or postdoctoral associates? Are there regular assessments of progress and background knowledge? Do supervisees and supervisors see the assessment procedures as satisfactory? For students, how are research topics refined early in training? For postdoctoral associates, how are research projects assessed to provide adequate stimulation and chance for advancement? Have appropriate times been scheduled for developing long-term programs of research and for identifying milestones? Do supervisors check research records for accuracy, quality, and completeness?

Checklist for Students

Have you developed a systematic work-plan and identified major difficulties and relevant references? Are your records in good order, so that you can find the relevant material about a problem you worked on 6 months ago? Do you have draft portions of any completed aspects of the research? Have you adequate opportunities for presentations about your work? Do others find your written work difficult or easy to understand? Have interim projects, such as figures, tables, or other matter, been identified for preparation during the project?

Mentoring

In 1997, the National Academy of Sciences published a handbook for faculty who want to develop good mentoring skills. It points out that mentoring is a personal, as well as a professional, relationship. Good mentors want to help their students get the most from their education, assist their socialization into the field, and aid them in finding employment. Students and postdoctoral associates benefit from having many mentors with different skills and priorities.

Successful mentors today must deal with issues involving ethnicity, culture, sex, and disability. Currently, women account for about half of the doctorates earned in the United States, while about 12% of the graduate enrollment is from US groups that are underrepresented in science and engineering. Non-US citizens make up about a third of the new science and engineering doctorates. Students may need access to a number of different faculty or graduate student peers for assistance. This may be particularly important when they come from different cultural or minority backgrounds. As faculty advisors, mentors must build mutual respect with the students and fellows whom they advise and supervise. Besides recognizing how issues of diversity may affect students' priorities and perceptions, faculty need to recognize that their students are likely to pursue careers outside academe and are legitimately concerned about time to degree and funding for their graduate education.

Junior faculty are also often in need of mentoring. They have the stresses created by considerably increased responsibilities for teaching and research and for professional service. Departments can establish numerous, albeit simple, ways to ease this transition, through appropriate workshops or by encouraging senior faculty to pair with junior colleagues. Departments can provide clear written guidance about tenure requirements and teaching policies and facilitate the acquisition of necessary resources for research, as well as nonresearch resources, such as childcare, which may be very important for entering faculty. They should arrange for frequent feedback

and evaluation. Minority and women faculty in particular may need protection from demands on their time created by the lack of others of their race or gender in their departments.

Students and postdoctoral associates often need assistance in mapping out career plans and in being introduced to contacts that may be able to help them. Students should be reminded that prospective employers also expect candidates to have other skills in addition to their competence in a chosen research field. Sometimes, mentors might need to provide frank and honest advice that identifies weaknesses but also indicates areas of strength that could be further enhanced. Over the course of the training, areas of weakness can also be corrected. Practice at teaching or making presentations, for instance, or critiques of draft grant proposals and resumes as well as research reports offer opportunities for improvement. Areas of strength might provide the basis for a good letter of recommendation from the mentor to the appropriate potential employer.

There are many ways that departments and institutions can improve the quality of mentoring, all requiring systematic and ongoing attention. Departments and institutions can track the progress of former students for information about careers. They can collect other relevant data or ask advanced students to assess how well their mentors or others have contributed to their progress. Institutions can schedule special activities and provide instructions on mentoring for new faculty and advisors. They can monitor faculty abuses and take a more active role in selecting faculty for advisory roles. They can provide workshops and discussions for students. They can encourage electives and other classes to broaden skills of students and postdoctoral associates.

All discussions of good mentoring and supervisory practice indicate that attention to these matters is imperative if trainees are to emerge with an intellectual and ethical framework that promotes research integrity and with some degree of satisfaction with their training experiences. Supervisors and mentors transmit to their students many of the attitudes and information needed to carry out significant research and good teaching and to practice responsible research. Faculty must recognize the need for human relationships to be built on respect and trust, as well as the special issues raised by the vulnerability of trainees.

In selecting mentors, students need to consider their publication records and national recognition, history of finding support for trainees, availability during the period of the student's training, prior training record and positions of recent graduates, practices of recognition for student accomplishments, and laboratory or other research arrangements. Students and postdoctoral associates should also recognize that mentors have different personalities. Some take an active interest and become involved in student projects; some are disengaged; some may develop friendships with their students and fellows. Each can pose difficulties for both parties. Open communication needs to be encouraged so that issues and potential misunderstandings can be clarified and any changes that might be necessary can be initiated in timely fashion.

To produce good work, mentors and trainees also need to be educated in the research standards of their fields. They need to be familiar with relevant codes of ethics. In experimental work, standards of laboratory practice or laboratory safety need to be discussed. This also holds true for standards of fieldwork and survey practice. Regulatory requirements concerning animal and human subjects need to be well understood. Standards for ethical practice of research with human subjects include matters of privacy and confidentiality, consent, and community protection. With regard to research in the social and behavioral sciences, complex questions concerning deception or stigmatization of individuals or communities may need particular care, especially in the context of research on vulnerable populations in other cultures. Mentors also bear special responsibilities when questions of the safety of students or postdoctoral associates might arise. All persons doing research should be familiar with definitions of research misconduct and the policies of their program and institution. Students must be trained in responsible use of statistical methods, where appropriate, and in the importance of stewardship of records and data, as well as in respect for ownership of ideas and intellectual property. Standards for responsible authorship and peer review also need to be understood and discrepancies that may exist between different fields need to be examined. These are areas where departments and institutions as well as professional associations and scientific societies have much to offer.

The study of science and engineering in society has begun to examine the social responsibility of science, engineering, and technology, focusing on the ethical assumptions and consequences that come in any framing of research questions, stipulations of methods and procedures, and confidence in results. This examination is likely to add an additional layer of complexity to discussions of responsible and responsive mentoring and supervision (Schienke et al., 2011).

Conclusion

For persons in academic research environments to achieve good results, they require and deserve assurance that others will do their share and that they will be protected if difficult problems arise. To foster this ethic, graduate departments or groups should develop adequate written statements of the terms of graduate study, including policies about conflict of interest, and should assign necessary duties to individual faculty members. These statements should be distributed to trainees. Individual faculty often have responsibilities for the admission of students, which allows them to assume similar responsibilities for advising students and postdoctoral associates and for placing graduate students in postdoctoral positions and jobs. Tasks that can help graduate students and postdoctoral associates succeed – such activities as writing proposals or research reports – can also be shared among faculty, as can assignments for making students aware of ethical aspects of research and professional activities.

Departments should create systems that specify advisors' duties and methods for evaluating their performance. Recent publications and guidance from national and international bodies and professional associations, as well as books and articles by individual scholars, can be helpful in developing materials and activities responsive to the needs of new faculty, postdoctoral researchers, and graduate students. Training for advisors continues to be needed. Increased attention to

structural reforms and ethical research practice might also lead to the diminution of research misconduct.

Meritocracy and Tokenism

Abstract

Meritocracy is relevant to a variety of influential social psychological frameworks: distributive justice, social identity theory, ideology, and inequality. Equity serves as the foundational justice principle for meritocracy. Social identity theory's concepts of boundary permeability and individual mobility reflect key aspects of meritocracy. Several theoretical perspectives explore the role of meritocracy beliefs in justifying and maintaining inequality. Contrasting the individual mobility of meritocracy is the highly restricted context of tokenism. Allowing individual mobility for a few disadvantaged group tokens can maintain intergroup inequality as tokens are quickly co-opted and the disadvantaged group abandons disruptive collective action for more benign individual responses.

Meritocracy

The concept of meritocracy can be found in a variety of highly influential social psychological frameworks. It is reflected in the distributive justice literature in discussions of the principle of *equity* (Deutsch, 1975; Tyler and Smith, 1998). It is also clearly implicated Social Identity Theory's (SIT) (Tajfel and Turner, 1979) concept of *individual social mobility*. Finally, it is named as an ideological belief that can serve to legitimize inequality between individuals and groups within a society (e.g., systems justification theory, Jost and Banaji, 1994). In this article, we will consider each of these manifestations of the concept of meritocracy.

Meritocracy is commonly defined as a social system where resources and/or status are distributed based on individual merit. This definition provides a statement about the objective criterion for determining whether a particular system qualifies as a meritocracy – the more each individual has earned his/her social and material place as a result of his/her own merit, the more the system can be described as meritocratic. However, this definition leaves open a key source of contestation – the meaning of merit. Although merit is often described as involving a combination of ability and effort, even this clarification leaves open to debate which particular abilities are relevant, what kinds of effort should count, and what the relative combination of these two ought to be. Thus, determining whether a system qualifies as a meritocracy can be highly subjective, and designating a given system as meritocratic usually involves building a shared consensus. Thus, rather than describing the objective state of affairs, labeling a given context a meritocracy is decidedly social psychological.

Meritocracy as Equity

Distributive justice involves people's evaluations of the fairness of the allocation of desirable outcomes across people. Deutsch (1975), in his influential summary of distributive justice, distinguished three basic principles that people endorse as fair depending on the particular social goals that are relevant to a particular relationship or social context (see Tyler and Smith, 1998). The principle of *equality* calls for the equal distribution of resources and is widely endorsed as the default principle in social settings were cooperation and harmony are primary goals. *Need* calls for unequal distribution of resources such that those who are most in need receive the larger portions. This principle is seen as appropriate where the goals are social welfare and responsibility. The principle of *equity* also calls for an unequal distribution of resources but holds that the ratio of any individual's inputs to outcomes should be equivalent to the same ratio of the person or persons with whom the individual is being compared. In other words, each individual should receive resources in proportion to their relative contributions. Some theorists have held that equity can be understood to be the general principle of distributive justice (see Adams, 1965; Walster et al., 1973). In fact, among some economists equity and justice are entirely conflated such that 'equitable' is synonymous with 'fair.' Although most social psychologists would see these as overstatements, equity is widely accepted as the preferred distributive justice principle in economic and competitive contexts (see Tyler, 2014). Thus, in capitalistic cultures such as North American (and perhaps other 'Western' nations), which focus heavily on competitive and economic relationships, the principle of equity (merit) is applied across a wide range of domains including educational, economic, political, organizational, and interpersonal.

While equality and need are inconsistent with meritocracy, the principle of equity serves as the primary justification for meritocracy. That is, a meritocracy is a system in which the principle of equity is upheld and it is generally believed that if individuals are talented enough or invest enough effort, they will receive a greater share of system resources and will advance up the social ladder. Given the relative ubiquity of equity as the preferred justice principle in individualistic/capitalistic cultures, it is perhaps not surprising that meritocracy has been described as America's 'dominant ideology' (Kluegel and Smith, 1986; McNamee and Miller, 2009). However, the recognition that equity is only one of at least three possible justice principles provides a basis for understanding why meritocracy, even when it is actually realized, can be rejected as unfair. For example, although we might find very few North American students who would reject meritocracy at the approach for distributing grades (a valued resource), we might find more variance in the endorsement of meritocracy as the primary strategy for distributing a professor's time. While the

best students might garner some additional attention, most would likely agree that a teacher's time should also be distributed more equally or perhaps on the basis of need. Thus, despite the strong support for meritocracy as a guiding cultural worldview, there remain contexts where meritocracy can be rejected in favor of another form for distributive justice.

Meritocracy as Social Mobility

The SIT (Tajfel and Turner, 1979) provides a framework for understanding when members of disadvantaged groups will accept their current low status, take individual action to improve their personal position, or take collective action to improve the status of their entire group. SIT proposes that individuals assess three *socio-structural variables* to determine which of these alternative responses they will take. They will assess the *legitimacy* of their group's low status – does the group deserve its disadvantaged position. They will consider the *stability* of the group's position – is it possible that the in-group can improve its relative standing and increase its share of the resources. However, a third and perhaps primary question is whether the boundaries between the groups are perceived to be *permeable* – is it possible for individual members to move out of their low-status group and acquire membership in a high status group. This third assessment is closely related to the concept of meritocracy, in that it involves assessing whether the social system is one in which individual effort leads to individual upward mobility.

SIT predicts, and considerable research has shown, that when the system appears to be open to individual mobility (when it is a meritocracy) disadvantaged group members will take actions designed to improve their personal position (see Ellemers, 2001; Wright, 2010 for reviews). They seek to demonstrate that they have the relevant attributes or can exert the necessary effort to move into a more advantaged group. Conversely, they are unlikely to engage in, or show support for, collective actions. Thus, SIT describes meritocracy as critical in maintaining the stability of the social order, because it encourages members of low status groups to seek personal solutions to their low status, and steers them away from disruptive efforts to improve the status of their entire group.

One reason seeing the system as meritocratic leads people to engage in individual rather than collective actions is that it focuses attention on individual identities and away from group identities (Wright, 2001). When rewards and social position appear to be result from individual effort and ability, group memberships become less important and thus group identities hold less motivational power (Derks et al., 2009). In addition, the apparent opportunity for individual mobility and the meritocratic nature of the social system also helps to support the view that the current social system, although unequal, is fair.

Meritocracy as Ideology

SIT's general claim that belief in individual mobility plays a critical role in preventing disadvantaged groups from challenging the social order is consistent with a growing literature that also focuses on meritocracy not as a structural reality but rather as a set of beliefs about how the social system works. Using terms like 'meritocracy beliefs' (e.g., Foster and Tsarfati, 2005), or 'meritocracy worldview' (e.g., Major et al., 2007) or 'meritocracy ideology' (e.g., Sengupta and Sibley, 2013), there is a growing social psychological literature that considers the motivational antecedents as well as the psychological and behavioral consequences of believing that the current system is a meritocracy.

Causes of Meritocracy Beliefs

Believing that one's place in the social hierarchy is determined by merit serves members of advantaged groups very well. This view provides justification for their privilege and allows for feelings of pride and satisfaction when comparing to those who have less. For the advantaged, meritocracy beliefs coincide nicely with the motivation to see oneself and one's in-group in a positive light (e.g., Levy et al., 2006). Thus, it is not surprising that Whites tend to endorse meritocratic beliefs more than Blacks and, for Whites, endorsement of meritocracy increases with personal socioeconomic status (Cokley et al., 2007).

However, endorsement of meritocracy beliefs is not influenced entirely by self- or group-interests. They are also the result of a desire to be accurate in assessing social reality. Thus, relevant and especially dramatic experiences can alter meritocracy beliefs. For example, Levy et al. (2006) showed that when considering the American government's woeful response to Hurricane Katrina, African-Americans reduce their endorsement of meritocratic beliefs – their belief that success results from hard work was undermined by what seemed like clear evidence to the contrary. The idea that relevant experiences can alter meritocracy beliefs is described nicely by Crosby and Ropp (2002) in their discussion of 'Awakening to Discrimination.' Women in academia who initially believed that their institutions functioned as meritocracies, through important trigger events or the slow accumulation of negative experiences, 'awoke' to the realization that sexist discrimination influenced their professional lives in ways they had not recognized. At this point, their faith in the meritocratic nature of their institutions was shaken. Conversely, dramatic changes in the social system can strengthen meritocracy beliefs. Kaiser et al. (2009) found that, immediately following Obama's election as president, participants from a number of ethnic groups concluded that racism was less of a problem and that anyone can achieve success through effort and perseverance.

A third explanation for why one might come to hold a meritocracy ideology centers around the premise that people have a general motivation to believe the world is just; that people generally get what they deserve and deserve what they get (Lerner, 1980; Hafer and Gosse, 2010). This general belief fosters a need to believe the broader institutions that influence our lives are legitimate and fair. This perspective has been advanced in John Jost and colleagues' *System Justification Theory* (e.g., Jost and Banaji, 1994; Jost and Hunyady, 2002), which holds that, in societies with obvious inequalities, there is a particular need for an ideology that can legitimize inequality. One such ideology is meritocracy.

Ledgerwood et al. (2011) provide experimental evidence of the effect of system justification motives and endorsement of meritocracy beliefs. In one of three experiments, participants read about studies that ostensibly tested the relationship between hard work and success. Given the dominance of

meritocracy ideology it is not surprising that participants judged those studies that supported the relationship between hard work and success to be of better quality and more convincing than those that refuted the effort/success relationship. However, the critical finding was that this 'pro-meritocracy' bias was made much stronger when participants were first exposed to a passage that threatened the legitimacy of their nation's social system. The authors conclude that their findings "suggest that the desire to preserve a view of the social system as fair and just serves to motivate the cognitive and behavioral defense of meritocratic beliefs."

Thus, it appears that endorsement of an ideology of meritocracy can result from: (1) a need to see oneself and one's group in positive light (personal or group self-interest); (2) a desire to accurately reflect what appears to be social reality (experience); and (3) the need to see the world as fair and thus to justify a social system with clear inequality in the distribution of resources and status.

Consequences of Meritocracy Beliefs

It appears that there may be a somewhat reciprocal relationship between self-interest and meritocracy. While the desire to see oneself in a positive light can serve to motivate endorsement of a meritocratic ideology, holding this worldview also has consequences for personal well-being. There is some evidence that meritocratic beliefs can have a positive effect on well-being. This may be particularly true for members of high status group (e.g., O'Brien and Major, 2005). As described earlier, believing that the current system rewards hard work and superior ability makes one's own (or one's group's) high status position a source of pride and thus contributes positively to self-esteem and life satisfaction. However, McCoy, et al. (2013) found that for members of both low and high status groups, endorsement of meritocracy beliefs was positively associated with self-esteem and physical health and that one of the primary reasons for this was that a stronger faith that one's society was meritocratic was associated with stronger feelings of control over future outcomes.

For disadvantaged group, however, believing that the system is meritocratic also implies that their current low-status position is deserved, and it would seem that this self-demeaning perspective should counter the potential benefits of a sense of control on self-esteem (Jost and Hunyady, 2002). Consistent with this, Quinn and Crocker (1999) investigating the relationship between endorsement of elements of a meritocratic ideology and self-esteem and depression among average weight and overweight women, found a positive relationship among normal weight women, no relationship among mildly overweight women, and among those who were most overweight the association was negative. In an effort to illuminate this somewhat murky relationship, O'Brien and Major (2005) offer a potential moderator. In a sample of African-Americans and Latinos endorsing meritocracy beliefs undermined well-being for those who were highly identified with their ethnic in-group, while these same beliefs were associated with higher well-being among African-Americans and Latinos who were low in ethnic identification.

Foster and colleagues (Foster et al., 2006; Foster and Tsarfati, 2005) provide another perspective and another moderator. They propose that this relationship between meritocracy beliefs and well-being is moderated by personal discrimination. Among women who experienced high personal discrimination, the belief in meritocracy was negatively correlated with well-being, while for those who experienced low personal discrimination the belief in meritocracy was positively correlated with well-being. This pattern held both when a measure of past experiences with discrimination was used (Foster et al., 2006) and when discrimination was manipulated in a laboratory setting (Foster and Tsarfati, 2005).

Major et al. (2007) reach a similar conclusion. They outline and test a *worldview verification model of self-esteem* which predicts that when experiences with discrimination threaten one's worldview, discrimination will impact negatively on self-esteem. If, however, experiences of discrimination confirm one's worldview, then self-esteem will be unaffected or even bolstered. Thus, for those holding a strong meritocracy worldview, discrimination will threaten that worldview and will undermine self-esteem. However, for those who reject the meritocratic worldview, experiences with discrimination will verify their worldview and thus will have little or even positive impacts on self-esteem. In three studies involving Latino-Americans and women, they showed this predicted interaction between endorsement or rejection of meritocracy worldview and perceptions of discrimination on self-esteem.

Meritocracy Beliefs and the Legitimization and Maintenance of Inequality

As discussed earlier, a meritocracy ideology not only describes the basis for upward mobility (merit), it also provides an explanation for the current status differences. If meritocracy exists, people 'at the top' have earned and thus deserve their advantage, while people 'at the bottom' also deserve their position. Thus, a meritocratic ideology supports positive stereotypes and attitudes toward advantaged group members, and negative attitudes toward disadvantaged groups.

Advantaged Groups

Just as it is not surprising that meritocracy beliefs are associated with more positive self-esteem among advantaged group members, it is also not surprising that it is advantaged group members who most strongly endorse these beliefs. What is disappointing is that endorsement of meritocracy beliefs is positively associated with denigration of low status groups. For example, Katz and Hass (1988) found a positive correlation between White Americans' meritocracy beliefs and anti-black attitudes. They also showed that priming meritocracy beliefs *prior* to filling out an anti-black attitudes scale resulted in even stronger anti-black attitudes (see also Biernat et al., 1996). Similar findings have been reported by Crandall (1994) in considering attitudes toward overweight people, and by Cozzarelli et al. (2001) in research on attitudes toward the poor. In every case, the more participants endorsed meritocracy beliefs the more they blame the low status group for their disadvantaged positions and the more negative their attitudes toward them.

Kaiser and her colleagues have also shown that negative attitudes about low status groups may not be directed equally at all members of those groups. For example, Whites who endorse a meritocracy worldview directed more negative attitudes especially toward members of minority groups who

demonstrated strong ethnic identification (Kaiser and Pratt-Hyatt, 2009). Similarly, Whites with strong meritocracy beliefs directed especially negative attitudes toward Blacks who attribute personal outcomes to racial discrimination (Kaiser et al., 2006). This finding points out another outcome of meritocracy beliefs. Since the existence of discrimination calls into question the claim that the system is meritocratic, advantaged group members who are strongly committed to meritocracy beliefs will be particularly unwilling to accept that discrimination and privilege play a role in determining one's place in the social hierarchy. Consistent with this, Knowles and Lowery (2012) showed that embracing meritocracy causes Whites to deny the existence of racial inequity not only as a means of justifying the social system but also in order to avoid the recognition of their own group's privilege. Thus, the denial of racial inequality that results from strong endorsement of meritocracy is tied directly to the previous discussion of the benefits of meritocracy beliefs for self-esteem and well-being. Advantaged group members who endorse meritocracy beliefs benefit in terms of self-esteem in part because this worldview allows them to deny the racial privilege they (and their in-group) enjoy.

Finally, Major et al. (2002) found that the more that members of an advantaged group (i.e., Whites and men) endorsed meritocracy beliefs the more likely they were to attribute negative outcomes they received from a low status group member (i.e., Latino-Americans or women) to discrimination. Similarly, O'Brien et al. (2012) found that endorsement or priming of meritocracy beliefs lead men to feel entitled to higher levels of pay. Paradoxically, the same beliefs that allow advantaged group members to deny the discrimination experienced by the disadvantaged out-group also allow them to feel more entitled to a large piece of the pie and to blame discrimination when they do not get that larger piece.

Disadvantaged Groups

As with the relationship between meritocracy beliefs and self-esteem, it is somewhat more difficult to understand why meritocracy beliefs ought to lead disadvantaged groups to legitimize the system in which they are disadvantaged. Nonetheless, Major and her colleagues have consistently demonstrated that strong endorsement or even temporary activation of elements of a meritocracy worldview can produce responses from members of low status groups that legitimize and perpetuate their disadvantage. For example, Major et al. (2002: Study 1) showed that among both Latino and African-Americans meritocracy beliefs were negatively related to the amount of discrimination they reported experiencing. In two experiments, they first measured Latino-Americans' (Study 2) and Women's (Study 3) meritocracy beliefs, and then participants were ostensibly rejected from a group activity by an out-group member (a White in Study 2 and a man in Study 3). Results showed that those who endorsed meritocracy beliefs more strongly were less likely to see this rejection as evidence of discrimination.

McCoy and Major (2007) replicated this general pattern of findings using a priming paradigm that allowed them to manipulate meritocracy beliefs. Relative to women in a neutral prime condition, women primed with meritocracy beliefs were less likely to see rejection by a man as discrimination, and also were more likely to stereotype themselves and women in ways that justified women's lower status. In a survey of working women (Hafer and Olson, 1993), stronger endorsement of meritocracy beliefs was associated with less dissatisfaction about both one's own low job status and the lower job status of women as a group. In addition, endorsement of meritocracy beliefs leads to less action to improve one's personal position, and importantly to less assertive action on behalf of women as a group. Thus, it was those who rejected meritocracy beliefs that were likely to take action to improve their personal position and to attempt to improve the status of the group as a whole. Finally, if one is unable to take direct action to improve one's personal position or the position of the group, one means of protecting one's well-being is to dis-identify with the domain (decrease the degree to which experiences in that domain are felt to be relevant for one's self-evaluation). However, Schmader et al. (2001) found that only those African-Americans who had rejected the dominant meritocratic ideology were able to engage strategies to dis-identify from a domain in which they were experiencing discrimination.

Thus, the ideology of meritocracy serves to maintain intergroup inequality by: (1) encouraging both advantaged and disadvantaged group members to ignore or even deny exiting privilege and discrimination; (2) providing justifications for opposition to equity-restoring policies; and (3) suppressing collective action among the disadvantaged.

Prescriptive or Descriptive Meritocracy Beliefs

An interesting conundrum emerges when we think carefully about what it means to endorse a meritocratic ideology. True meritocracy in which opportunities and rewards are distributed only on the basis of individual merit can only be realized in an unbiased system (Crosby, 2004; Smith-Winkelman and Crosby, 1994). The existence of discrimination directly undermines meritocratic principles. Thus, it would be logical to predict that those who strongly believe in meritocracy should be vigilant for evidence of group-based discrimination, should oppose these violations of meritocracy, and support efforts to change the system to remove them. Yet, as we have just reviewed, a great deal of research appears to show precisely the opposite relationship such that endorsing meritocracy results in the ignoring and legitimizing of discrimination and opposition to efforts to reduce it. Son Hing et al. (2002, 2011) provide a rather elegant solution to the conundrum by distinguishing between what they call *descriptive meritocracy* and *prescriptive meritocracy*.

Descriptive meritocracy is the belief that the current system, in fact, is a meritocracy; that personal effort and ability indeed does determine one's place in the system. This is the type of meritocracy ideology that has been measured in most of the research that we have just reviewed. In contrast, prescriptive meritocracy is the belief that merit is what ought to determine outcomes and status within the system. Using the terms described earlier in this chapter, prescriptive meritocracy involves a strong commitment to the justice principle of equity. Although prescriptive meritocracy beliefs can lead to 'principled' opposition to some forms of affirmative action to redress discrimination, when those programs are perceived to violate the merit principle, Son Hing et al. (2002) have shown that

prescriptive meritocracy beliefs can facilitate acknowledgment of inequality and increase support for affirmative action programs that are perceived to be removing these merit violations. In fact, Son Hing et al. (2011) conclude that their research shows that "beliefs that meritocracy ought to exist are independent of beliefs that meritocracy does exist. The latter – beliefs that meritocracy does exist – can serve as a hierarchy–legitimizing ideology that justifies current societal inequality. In contrast, the former beliefs – that meritocracy ought to exist – reflect a preference for a particular norm of distributive justice and can in fact drive support for policies that challenge the status quo." (pp. 447–448)

Tokenism

Meritocracy is often contrasted with a system where group boundaries are entirely impermeable and one's position is entirely determined by one's group membership (e.g., van Zomeren et al., 2008). However, in many contexts in contemporary societies the system is neither entirely meritocratic, nor is upward mobility impossible. Instead, barriers and restrictions result in only some of the qualified members of the disadvantaged group gaining access to advantaged positions. Often the restrictions can be quite severe and the result is a situation described as *tokenism* (Wright et al., 1990) – *an intergroup context in which the boundaries between the advantaged and disadvantaged groups are not entirely closed, but where there are severe restrictions on access to advantaged positions on the basis of group membership*.

The vast majority of work on tokenism has considered the experiences and actions of the 'tokens' themselves – those few individuals who, despite the barriers, gain access to advantaged positions – but there is also some work on the perspective of the rest of the disadvantaged group who are forced to remain disadvantaged. The theme that emerges from both of these literatures is, rather than being a benign step in the slow process of social change, tokenism creates new impediments that serve to legitimate and perpetuate the present social arrangement.

Successful Tokens

Much of the early research investigating the experiences of successful tokens (e.g., women and minorities in settings that were traditionally the exclusive domain of white males) centered on the psychological and performance consequences of interactions between tokens and majority group members. The dominant conclusions from this literature are that (1) tokens often do not receive treatment and status equal to their non-token colleagues (Kanter, 1977; Sackett et al., 1991; Yoder, 1994); (2) tokens often find their position difficult and dissatisfying and may seek to leave the group (e.g., Cohen and Swim, 1995; Stone, 2007); and (3) token status can result in deficits in performance (e.g., Saenz and Lord, 1989).

Often the problem for tokens is twofold. First, their small numbers make them highly visible and they often garner more scrutiny. While this can sometime lead to them being seen as more important to the group (e.g., Fuegen and Biernat, 2002), the highly visible nature of their group membership often leads them to be seen more in terms of group stereotypes. When combined with the need to conform to the norms and expectations that all group members feel, being seen in terms of the stereotypes of one's disadvantages group can make it difficult to fit in. In an effort to solve this problem, women in male-dominated workplaces, for example, may attempt to adopt a more masculine style in line with the normative culture, and while this may garner some recognition for competence, it may also be seen to violate prescribed gender norms leading to unpleasant backlash and social disapproval (Benard and Correll, 2010; Phelan and Rudman, 2010).

Biernat et al. (1998) in a study of women in the American military showed that at times token women will also provide self-evaluations that are more negative than the evaluations they receive from their peers. The authors propose that these are the product of self-stereotyping, and point out that these negative self-evaluations did not persist when the number of women in the group increased. Thus, because tokenism can heighten the salience of one's group member, it may at times also heighten the salience and use of negative self-stereotypes.

Finally, Karrasch (2003) investigated commitment in the US military and found that the often reported tokenism experiences in women (e.g., feeling highly visible, isolated, or trapped in fulfilling stereotypes) were correlated with lower *affective* commitment to the military. However, tokenism experiences were also positively related to *continuance* commitment, the perception that there are limited or no better alternatives. It was also shown that *affective* commitment predicted leadership behavior, while higher levels of *continuance* commitment were associated with fewer leadership behaviors. So, it appears that tokenism experiences reduce those aspects of commitment that are associated with success, while at the same time discouraging leaving for the fear that alternatives will be even worse.

In contrast to considering the direct experience of the tokens themselves, others have taken a somewhat more intergroup approach and have investigated the impact of token status on token's support for action designed to improve the general position of their group (e.g., Ellemers et al., 2004). If disadvantaged group members who become token members of an advantaged group were to use their newly acquired status and privileges to aid their disadvantaged group, they could be important contributors to social change. While some researchers have found that, in some cases, tokens do continue to assist other women to move up the social hierarchy, the majority of this research is less optimistic. Wright and Taylor (1999) conclude that tokens may often be co-opted by the advantaged group and are unlikely to support collective attempts by their group to change status quo. Although successful tokens recognize the illegitimacy of tokenism, they are unwilling to support actions likely to correct this injustice. This failure to support assertive action may lead others to misrepresent tokens' perceptions and feeling. The lack of support for collective social change sends an implicit message of support for the present social order, in effect legitimizing the continued discrimination against the disadvantaged in-group. Similarly, Derks et al. (in press) summarize their extensive research on token women by saying that "rather than fighting gender inequality as a broader concern – through collective

mobility – these women accept and legitimize the status quo in which women as a group are disadvantaged, and use this gender-based inequality to advance their individual career mobility."

In summary, tokens face formidably personal struggles themselves and thus it is perhaps not surprising that they are either unwilling or unable to 'carry the torch' of social change and champion the cause of the larger disadvantaged group.

The Disadvantaged Group

Despite the success of a few, for the vast majority of the disadvantaged group, tokenism results in the perpetuation of their disadvantaged status. Pettigrew and Martin (1987) suggested that awareness of the difficulties experienced by successful tokens can lead to lowered aspirations among other members of the group. In addition, a number of studies (e.g., Barreto, et al., 2004; Lalonde and Silverman, 1994; Reynolds et al., 2000; Wright, 2001) reveal that, while complete boundary impermeability – a closed social system – produces strong interest in collective action, when as few as 2% of the qualified members of the disadvantaged group are allowed access to advantaged positions collective action is replaced with a preference for individual action. It appears that the slightest hint of permeability undermines collective action.

Tokenism may have this effect because it makes salient personal identities and encourages interpersonal comparisons with the few successful tokens (Wright and Taylor, 1998). Further, tokenism may obfuscate assessments of the legitimacy and stability of the in-group's low-status position (Wright, 1997). Danaher and Branscombe (2010) have shown that token hiring practices while recognized as unfair and demeaning to the in-group nonetheless maintain organizational identification among disadvantaged group members. They found that tokenism keeps women participating in the system at large, by maintaining individual mobility beliefs, and within their local organization, by maintaining organizational identification. Thus, "token practices fool women into thinking that token conditions are positive for their group by making group boundaries appear to be permeable and legitimate."

Ellemers and Barreto (2009) point out that tokenism is but one example of the ways that social structures and discriminatory practices can elicit from those who have disadvantaged beliefs and behaviors that help to perpetuate the *illusion of meritocracy* – the belief that, despite all the evidence to the contrary, individual merit and not group membership determines one's opportunities and one's place in the social world.

Abstract

Over the period of three quarters of a century, Robert K. Merton demonstrated an impressive productivity as a sociologist of different specialties. First and foremost, he contributed to sociological theory and is the founder of the sociology of science. He also contributed to the sociology of knowledge, organization theory, deviant behavior, mass communications; and the professions and less broadly recognized fields of sociological semantics, and the sociology and history of ideas. The broad range of subject matters he studied and his close reading of former contributions to sociology resulted in Merton's identifying and labeling such social phenomena as the self-fulfilling prophecy, unanticipated consequences, focus groups, and role models, among a great many others. Given this wide spectrum of conceptual and empirical contributions and Merton's plea for middle-range ambitions in theory building, he will continue to be a sociologist of consequence.

If social scientists and authors from other branches of scholarship would always name the originators of neologisms and concepts they use, one name would probably surface much more often than any other: Robert K. Merton (following his own style of writing, which exhibited a strong inclination toward acronyms, I will refer to him as RKM hereafter). He coined, borrowed, polished, refined, and reformulated concepts more than any other social scientist. Along that way, he also introduced a new term for this type of work: initially 'conceptual analysis' (Merton, 1968: 168–171) and later on 'reconceptualization' (Merton, 2004: 245–260). Without RKM, not only would the language of the social sciences be more meager, but also the vernacular, the vocabulary of ordinary life. 'Self-fulfilling prophecy,' 'role model,' 'dysfunctional,' 'focussed interview' (see Merton, 1987a for an explanation of the double-s), 'serendipity,' and other Mertonian coinages traveled smoothly into the lexicon of middle-ranged educated people, not only in the Anglophone world but also beyond. Other Mertonian reconceptualizations remained inside the walls of academia: Thomas theorem, Matthew effect, latent versus manifest, opportunity structures, etc.

The *Oxford English Dictionary*, a source RKM regularly consulted both to examine changes of meaning over time and to encounter unknown but telling expressions (Merton, 2004: 233–244), cites his publications four-dozen times to document trajectories of semantics. Going through these quotations, one can see that RKM both codified meaning, so his wording functioned as an exemplar, and invented, sometimes unsuccessfully, new expressions. To give only a few examples: aberrant, avocational, backfence, benchmark, boondoggling neurosis, caste hypogamy, the local and the cosmopolitan, Matthew effect, modal personality, opinionnaires, out-grouper, pilot study, point-to-point correlation, prestige-structure, problematics (the principal problems), quantitativist, retreatism, ritualism, role, role model, subsurface trends in class structure.

On a par with augmenting scholars' and lay people's vocabularies come RKM's publications. Since the rules of the academic game require participants to refer sources, we can say with some certainty that several of his papers and some of his books became what Eugene Garfield called 'citation classics' (one of the many admirers of RKM and his oeuvre). Garfield, the founder of the citation index business, has been encouraged and tutored by RKM and listed some of his work in the category of highest cited papers (Garfield, 1963).

To better understand RKM and his intellectual distinctiveness beyond citation counts, it is advisable to take a look at the format of RKM's writings and publications. The majority of the books authored by RKM fall in the genre of collections and only a small minority fit the prerequisites of a monograph. In contrast to what happens elsewhere in academia and to other authors, RKM's collected volumes are much wider known than most of his monographs (Merton, 1949, 1957a, 1968, 1973, 1976, 1982, 1996). Paraphrasing one of his well-known phrases, one could identify his writings as middle-range texts. They do not try to cover huge intellectual landscapes but selected regions, which are investigated not from an eagle's perspective but by someone much closer to those investigated. RKM only rarely engaged in the textbook standards of participant observation as his preferred mode of data collection, but his writings show that he always tried to get as close to the field he analyzed as possible. One could call what forbade RKM to write about things strange to him were his need for familiarity coming up against inaccessibility in a researcher's time frame (see his explanations on strategic research event in (Merton, 1987b: 11–15)). To consult another of RKM's favorite lexicographic sources, most of his texts are essays in the strict sense of the definition of this genre by one of the founding fathers of modern lexicography, Samuel Johnson (1709–84): 'First taste of any thing,' 'a loose sally of the mind, an irregular, undigested piece, not a regular and orderly performance.' This circumscription might sound strange in the ears of present-day readers, but it is in accord with one of RKM's lasting convictions regarding the status of sociology as a science. In his early years, he stuck to the conviction that sociology is a young member of the science family and has a long way to go before arriving at the mature level of its siblings (Merton, 1945a). In later years, RKM bid farewell to the idea of sociology's quick maturing and even conceded that sociology might never become a science *more geometrico*. Long before he changed his mind with regard to the maturity of his craft, he had chosen the less scientific format of the essay as the most appropriate for his intellectual ambitions and inclinations. Enterprises less academically mature than neighboring rivals, e.g., sociology

compared to physics, ask for writing styles and publication formats that avoid fixations and stringencies and favor explorations. Here as elsewhere in the social world, the alignment of the causality's arrow is not carved in stone and correlation prevents hasty interpretations. But who wants to rule out that someone with a preference for the literary form gravitates toward subjects that best fit his format of choice?

Merton's Paradigmatic Vision

Given the probing style of his writing, it is anything but easy to summarize RKM's intellectual contributions or to identify the core of his intellectual ambitions. At least since the first volume of collected papers, *Social Theory and Social Structure* (abbreviated by RKM usually as STSS), appeared in print in 1949, a regular criticism he had encountered was that he did not provide an encompassing theory. While this may be true, ultimately this truth depends on the meaning one assigns to the highly equivocal term 'theory,' as RKM himself outlined in the introduction of the first two editions of STSS, which became two separate chapters in the third edition.

RKM did not provide any general theory such as Darwin's theory of natural selection, or Freud's theory of the role the unconscious, or Weber's theory of occidental rationalism – theories whose core can usually be summarized in one sentence. Instead, he outlined the panorama a theory should try to cover. RKM does not provide simple sets of propositions and call them a theory, but labors on several aspects and elements of theoretical relevance. Therefore, his theories are seldom encompassing but hint toward what one should keep in mind when examining particular aspects of social life. Given the collectively shared mood not only of sociologists but also of neighboring social scientists in the middle of the twentieth century, it is surprising to see that RKM was not in favor of grand theories that are supposed to explain everything out of a handful of concepts and vaguely defined relations between them. Early on, RKM distanced himself from Parsons' endeavor to develop such a general theory (because he did this politely and did not orchestrate it as a parricide like many other unruly disciples, most later generations of sociologists did not notice the depth of differences between these two, Merton, 1980). Parsons' claim, that his general theory will be different from the speculative theories of Spencer and his contemporaries, did not persuade RKM. Looking back to the years following the end of World War II, one needs to highlight that it was not very fashionable to challenge the highfalutin ambitions proposed by Parsons, then widely admired.

Another interpretation of theory could point to the generalization one strives for or hopes to achieve. The more generally applicable a proposition, the more likely we could call it a theory. What others labeled a theory RKM called a 'paradigm,' very early on. He made use of this term first in 1945 when he outlined a paradigm for the sociology of knowledge (Merton, 1945b), in 1949 when he elaborated one for functional analysis, and later one for structural analysis (Merton, 1975). He also used the same strategy in other contexts: e.g., in his reconstruction of the meaning of anomie (Merton, 1938c, 1995), in his attempt to elaborate patterns of intermarriage (Merton, 1941), and elsewhere. RKM must have been surprised, to say the least, when he had to recognize that someone else became designated as the originator of the term paradigm. However, his historical notes on Thomas Kuhn's trajectory do not show any jealousy (Merton, 1979, 2004: 264–269). According to RKM, paradigms are orienting, which means that they are an outline for what a researcher should look for; they direct research by providing basic queries, list variables, and outline possible connections between elements under scrutiny.

Contemplating about the properties of what could be reasonably called a sociological theory, RKM arrived at a level below the generalized ones, which Parsons and nearly all earlier theorists preferred; he gave it the versatile title "theories of the middle range: theories that lie between the minor but necessary working hypotheses that evolve in abundance during day-to-day research and the all-inclusive systematic efforts to develop a unified theory that will explain all the observed uniformities of social behavior, social organization, and social change" (Merton, 1968: 39).

This notion and understanding of theory work in sociology has been challenged, repudiated, and most of all misunderstood. Its meaning and range is debatable, but RKM devoted more energy and effort to contribute theories of this type rather than defending his concept as such. It is nearly impossible to provide a list of all Mertonian theories of middle range, but some of them will be covered below. An intrinsic problem in identifying these kinds of theories lies in the difficulty distinguishing theories from concepts in RKM's writings. Take as an example one of his most famous expressions, the self-fulfilling prophecy. Is it a middle-range theory, a mechanism, as some later admirers of RKM proposed, or is it anything more than a cleverly labeled concept? The scope of applicability of this 'dynamic social mechanism,' as he himself classified this concept-theory (Merton, 1968: 182), is nearly limitless: one should not be surprised to find proofs of it in ancient time, in far away corners of today's world, in highest developed as in disadvantaged, underdeveloped stages of mankind – in a word: it fits the criteria of universalistic applicability, much more than the definition of middle range would ask for. RKM himself subsumes the self-fulfilling prophecy, its counterpart the suicidal or self-destroying prophecy together with the "unanticipated consequences of action or decision or belief" (Merton, 1968: 182) as one pattern of latent functions. In comparing this concept with another famous reconceptualization of RKM, the interpretation and reformulation of Emile Durkheim's anomie, one wonders whether the range of these 'types of individual adaptation' – conformism, innovation, ritualism, retreatism, and rebellion – is broader than the former mentioned ones or not. Just to mention one aspect of a comparative analysis, one could imagine a human group, which cannot realize its culturally defined goals directly but in which the mechanism of self-fulfillment operates, nonetheless. Or to put it in another way: both self-fulfilling and anomie mechanisms seem to be valid in and for nearly every type of social group but neither help us to make distinctions between these groups, societies, or other larger social structures. The transition from concept to theory has

not been prescribed by RKM. We are, therefore, more or less free to choose arbitrarily between them.

Beneath high-abstraction and low-verifiable validity, to which RKM contributed in his earlier career more heavily than later on, he made a large number of contributions to sociological knowledge, only some of which can be covered in such a condensed tribute to a scholar who authored his first published paper at the age of 24 and who handed over his last manuscript to the publisher at the age of 93. In the seven decades between 1934 and 2004 when *The Travels and Adventures of Serendipity* came out in English posthumously (a translated version had been published in Italy in 2002), RKM published 20 books, more than 150 articles, numerous introductions, prefaces and, book reviews and has been responsible for coediting two huge compilations of reprints: 61 dissertations in sociology and 100 'classics, staples, and precursors in sociology.'

A Selection of RKM's Substantive Contributions

If we distinguish between core convictions and lasting engagement in a scholar's oeuvre, I would like to select five such durable concerns in RKM's case.

His very first book, a revised edition of his 1936 Harvard PhD thesis, came out in 1938, not the best time in contemporary history to draw the attention of academia to the work of an unknown youngster (Merton, 1938a). Contrary to the unpromising environment, this juvenilia impressed experts then and now (Cohen, 1990). *Science, Technology and Society in Seventeenth Century England* had been produced under the tutelage of the eminent historian of science, George Sarton. RKM had conducted research on the formation of modern science in England in the early days of the Royal Society. The history of science context did not keep the trained sociologist from applying contemporary inventions of social research methodology, e.g., he contemplated about how to draw a sample from the *Dictionary of National Biography* and ended up with about 6000 biographical data sets of individual scholars; he conducted a content analysis of the early volumes of the *Proceedings of the Royal Society*; and he paid tribute to the embeddedness of the work of these scientists in larger public affairs of building vessels, improving navigation, and designing weapons. Together with some related articles and strengthened by the fact of a reprint of core chapters of the dissertation in consecutive editions of STSS, RKM became the founding father of sociology of science. During the seven decades of his academic life, RKM remained concerned with this special branch of sociological research (Cole and Zuckerman, 1975). In 1937, while still a graduate student, Sarton made him an associate editor for 'Social Aspects of Science' in the editorial team of the journal *Isis*. RKM demonstrated his continued interest by publishing and commissioning trend reports and some of the first bibliographies (Barber and Merton, 1952; Barber, 1952, 1956). Later in life, he devoted his ASA presidential address to his specialty (Merton, 1957b), directed some dissertations and well-funded major research projects, helped to create bodies for international exchange of ideas and research findings within this group of specialists (RKM was the first president of ISA's research committee sociology of science), and was able to establish good relations to scientists themselves. Evidence of that latter point is that he was the first and is still the only social scientists who received the *National Medal of Science* from the hands of the US president.

A second field of investigations, which occupied RKM for some years, was the result of his close collaboration with Paul F. Lazarsfeld at the Bureau of Applied Social Research (Lazarsfeld, 1975; Merton, 1998). It was then labeled 'mass communication research' and would fit today into 'sociology of culture' and 'cultural sociology' properly. Back in the 1940s, recent societal transformations attracted the attention of social scientists: the role of radio, meaning and workings of propaganda, and political attempts to make use of both technologies. The most visible result of RKM's involvement in this area is the small monograph *Mass Persuasion*, which he wrote with the assistance of Marjorie Fiske and Alberta Curtis (Merton et al., 1946, 2004). The underlying study was the birthplace of the focused interview, which became subsequently adapted and modified into focus group studies, prompting RKM to publish a whole manual of procedures (Merton, et al., [1956]1990). In *Mass Persuasion*, the team of investigators interviewed people after they listened to the third all-day war bond drive by a then well-known singer and radio talk show host, Kate Smith. Combining content analysis and focused interviews, the research team, which had been formed on short notice (Lazarsfeld called this firehouse research: Lazarsfeld, 1969: 313), presented both an analysis of the persuasiveness of a mass culture heroine and an insightful exploration of what made this program attractive for listeners. In a paper RKM published around this time together with Lazarsfeld (Lazarsfeld and Merton, 1948), the two authors elaborated what later on became known as the Columbia tradition in mass communication research, a middle-of-the-road position that accredited the critical wing of social analysis with some validity: they called it 'narcotizing dysfunction of media' but insisted that media fulfilled social functions too: status conferral, on the one hand, and enforcement of social norms, on the other. The fact that RKM's involvement in empirical social research brought two monographs mainly authored by him to life is in itself telling regarding that his main interests were elsewhere. Two chapters in STSS's part on theoretical sociology, which were also published independently as a book (Merton, 1967), devote to this interrelationship in some detail: "The Bearing of Sociological Theory on Empirical Research" and "The Bearing of Empirical Research on Sociological Theory" (Merton, 1968: 139–171).

Judging by the academic echo it evoked, one of RKM's earliest papers surpass all others: "Social structure and anomie," first published in 1938 in *American Sociological Review*, not only became a citation classic but also had lasting influence on the sociological study of deviant behavior. For decades, no student of criminology, deviant behavior, and neighboring fields could evade the five types of individual adaption, or strain theory as an important way to understand deviance. RKM's interpretation of Durkheim's concept of anomie remains influential and controversial at the same time: 40 years after the publication one of his students gave an overview on the reception (Cole, 1975) and

three quarters of a century after its first print RKM's paper got quoted 3797 times in Google Scholar (August 2014). RKM himself contributed to the debate on anomie theory, further elaborated the meaning of opportunity structures (see his retrospective memoir: Merton, 1995), and used it as an analytical model for composing a reader together with Robert Nisbet on *Contemporary Social Problems* (Merton and Nisbet, 1961). Between 1961 and 1976, when this reader appeared in its fourth edition, it was formative for thinking about forms of deviance, at least in American colleges and universities.

At any rate, two more lines of thinking can be identified as characteristic of RKM: His devotion to the history of the sciences and social sciences and his elaboration of what he called sociological semantics. The interest in the past of his own discipline started for RKM from his conviction that re-conceptualization and taking a second glance at past contributions to sociology are fruitful endeavors. Later in his career, he took his own life and work as an exemplar to demonstrate the relevance of archived material, like unpublished correspondences, to grasp particular developments in sociology in more detail. He restrained from writing a full-fledged autobiography but penned several shorter memoirs, most famously the Charles Homer Haskins lecture he gave in his hometown Philadelphia in April of 1994 (Merton, 1994).

One could argue that autobiographical details of a scholar's life do not influence the validity of his pronouncements and argues even more strongly that hobby horses do not belong to an academic balance sheet. But a portrait of RKM would be lacking in color and integrity if OTSOG would not be mentioned. The acronym stands for *On the Shoulders of Giants*, originally a somewhat lengthy letter to his friend, the Harvard historian Bernard Bailyn, typed during some leisure time at the end of 1957. Eight years later, RKM's lengthy letter became a book and has since been translated and gone through at least three editions. At the time when the original manuscript has been produced, and even when the first printed version appeared in 1965, only few readers knew that this 'Shandean Postscript' was nothing like a 'singleton' (cf Merton, 1961a). Around the time of the letter writing, which resulted in OTSOG, RKM was working with his colleague Elinor Barber on a manuscript that only appeared some 40 years later. The book (Merton and Barber, 2004) contains a 70-page afterword where RKM elaborates on the evolvement of his interest in the serendipity pattern and his plea for what he then called *sociological semantics*. By that he meant the analysis of changes in the meaning of widely used concepts or terms as well as the investigation of sociological characteristics of its creators, providers, users, and those ignoring such inventions.

An Improbable Life Trajectory

Given this short overview of this scholar's oeuvre, the reader might want to know how all this could have been accomplished by one man. To put it in a slightly different way: Who was the man behind all these publications? The author was not born in 1910 but only some 15 years later, as the interested reader first had a chance to read in a portrait of RKM, which was published in the widely distributed magazine *New Yorker* by the science journalist Morton Hunt (Hunt, 1961). About 34 years later, RKM confirmed the story in his Haskins lecture of 1994: The newborn son of Yiddish-speaking immigrants from Russia goes under a very different name in 1910 and changed it to a more American sounding one when he aspired to start a professional career as a magician. Before this, encouraged by his mother and his sister's husband, he adopted both reading and magic as habits. Due to friendly female librarians in the neighboring library, established by a generous gift from Andrew Carnegie, one of the Gilded Age's robber barons, young not-yet-Robert earned a good education in "literature, science, and history, especially in biographies and autobiographies" (Merton, 1994: 343). In Philadelphia, RKM attended high school and continued into college at the then noncredited Temple University. There he met his first sociology teacher, George E. Simpson, who recruited the sophomore, now known as RKM, as a research assistant to help him finish his own dissertation on *The Negro in the Philadelphia Press*. From Simpson, RKM learned sociological techniques of data collection and analysis. His mentor also took the undergraduate student to the Annual Meeting of the then American Sociological Society. Back then, the number of attendants was small enough that an ambitious young no-name could chat with an established older man. Pitirim A. Sorokin (who, just as RKM's parents, was born in Tsarist Russia but was neither Jewish nor Russian, but belonged to the Finno-Ugric minority of Komi) encouraged RKM to apply for a scholarship for graduate study at Harvard University, where Sorokin recently had been hired to found the department of sociology. From 1931 onwards, RKM spent 7 years around Harvard Square where he met some of his future mentors and friends. Together with Sorokin, he authored at least three papers and learned Italian over a summer break after Sorokin's request (visiting professor Corrado Gini's English was insufficient for teaching). Sorokin and RKM drifted apart partly due to the latter's choice of his dissertation topic (Merton, 1989). As already mentioned, Sarton took over as mentor and role model: from him, RKM learned a new style of writing and judging others' contributions (Thackray and Merton, 1972). RKM's admiration for the Belgian-born polymath never receded (Merton, 1985). Then Talcott Parsons entered the circles of the graduate student, which brought RKM back on route to a career in sociology (Merton, 1980). The fact that he remained an underpaid tutor in Harvard's department could not have to do with the pervasive anti-Semitism held by Harvard's WASPs because RKM's Jewish origins were not known publicly until his disclosure in 1994. Given RKM's productivity before he reached the age of 30 (one book, more than a dozen articles, including some which became classics (Merton, 1936, 1938b; Merton and Sorokin, 1937), and a bunch of book reviews), it is not a big surprise that other universities were eager to hire the young Harvard man. From 1938 to 1941, RKM took a detour through the Deep South and acted as chairman and professor at Tulane University in New Orleans. Around this time, RKM must have realized that he may once become famous and started to administer his correspondence and files rigorously and easy to navigate for later users of his papers, stored at the

very university where he spent most of his career: Columbia University in the City of New York. There he started as an assistant professor on a post, which has been split in two because the two powerful members of the department could not agree on one candidate. The tacit assumption of the department's rivals and other Columbia people must have been that within a short period of time only one incumbent will survive. Quite the contrary happened – very much to the advantage of sociology. RKM and the nearly 10-years older Paul F. Lazarsfeld did not battle each other but collaborated. The story of how this relationship started has been initially told by the *New Yorker* and then by Lazarsfeld in the festschrift RKM received at his 65th birthday (Lazarsfeld, 1975): Instead of having the intended first dinner at the Lazarsfeld's, the two men went downtown to a radio studio to conduct an urgent radio-audience study, leaving their astonished wives behind. When the job was done, both continued talking at the Russian Tea Room until long after midnight.

Lazarsfeld was able to persuade RKM to join him at the newly renamed Bureau of Applied Social Research where RKM remained, in one or another function, until its end. The relationship between the Viennese-Jewish upper-middle-class mathematician-turned-into-social researcher and the Philadelphian slum dweller and Harvard alumnus became one of the highly unusual success stories in academia. They nurtured several cohorts of first-class students who became fellow sociologists – just to mention some from the earliest days: Peter M. Blau, James Coleman, Lewis Coser, Rose Laub Coser, Alvin Gouldner, Seymour Martin Lipset – and dominated American sociology for a while. The highly improbable collaboration stretched out beyond the Columbia campus. RKM also acted as gatekeeper at several publishing houses and foundations: at Ford, Guggenheim, the Palo Alto Center for Advanced Study in the Behavioral Sciences, MacArthur, Russell Sage. At other spending bodies, RKM acted either as board member or reviewer. It is not inconceivable that such a powerful position generated some jealousy.

There is another trait in RKM's performance, which needs to be mentioned: His refusal to take positions in public. RKM never performed as a public intellectual, never wrote op-eds, appeared at public events or sent letters to the editor (for one exception see Merton, 1961b). He started his days as early as 04.30 in the morning and continued working in his home office until he reached a degree of exhaustion or feeling of completeness. He then walked to his more publicly available office at Columbia or his small cubicle at the Russell Sage Foundation's headquarter where he enjoyed the status of Foundation Scholar. Apparently, he did not need much sleep because one could also meet him later in the day or at night. RKM seemed to enjoy living in New York City and meeting people from several corners of this quintessential professional metropolis. But he always remained a private person and never joined movements, organizations, or any other forms of public engagements. He rejected calls to other places, even if they were Oxford. His political convictions shine through in several of his papers, most explicitly in response to the Nazi movement in Germany and his concern with racial discrimination in his own country (Merton, 1942, 1948).

Legacies

A decade passed since RKM died on 23 February 2003, but it seems he and his works are more appreciated today than ever. During his lifetime, he received two festschriften (Coser, 1975; Gieryn, 1980), two volumes with critical comments on his work appeared (Mongardini and Tabboni, 1998; Clark et al., 1990) and two books introduced and critically commented on his work (Sztompka, 1986; Crothers, 1987). Criticism has been raised, but never reached the level of the diatribes against his friend-and-teacher Parsons and his collaborator-and-friend Lazarsfeld (cf vicariously for others Mills, 1959; Gouldner, 1970).

The biggest influence of RKM is epitomized by one of his concepts: obliteration by incorporation. But as mentioned above, some of his contributions are still related to him as their originator. Over the last couple of years, at least three more tribute-like collections appeared after conferences in Budapest, New York, and Warsaw (Elkana et al., 2011; Calhoun, 2010; Mica et al., 2011), complemented by short introductions to his work in German and French (Mackert and Steinbicker, 2013; Saint-Martin, 2013).

It might be neither a self-fulfilling nor suicidal prophecy to say that both RKM's published work and the immensely rich collection of manuscripts, correspondences, and other material stored and cataloged at the Rare Book and Manuscript Division of Butler Library, Columbia University, as the Robert K. Merton papers will find further interpreters assessing matters from the viewpoint his shoulders offer.

Abstract

Mesoamerica is a geographical and cultural area that includes most of Mexico and parts of Central America where an ancient civilization thrived between 3000 and 500 years ago. The states and societies that formed ancient Mesoamerica shared a number of characteristics, including: intensive agriculture, markets, urbanism, writing, religion, calendar, social organization, and monumental architecture. However despite a high degree of cultural, ideological, and economic integration, Mesoamerica remained politically fragmented throughout its history. In this article, I attribute the persistent fragmentation to the cross-scale interaction of interregional trade and regional-scale political economic strategies and use world-system theory and collective action theory to elucidate their interaction.

Introduction

Prior to the Spanish Conquest, the cultural area known as Mesoamerica (Kirchhoff, 1952) had developed a thriving civilizational tradition over a period of approximately 3000 years. Thus, the term Mesoamerica makes reference to both a culture area and a civilizational tradition (Blanton et al., 1999; *see* States and Civilizations, Archaeology of). Complex social, political, and economic processes marked this tradition. Specialized merchants traveled the length and breadth of Mesoamerica, trading in special international markets (entrepôts), as well as the major regional market places. Most importantly, the long-distance exchange fostered by these merchants moved ideas, goods, and people among a vast array of regions and thereby welded Mesoamerica into a single thriving civilization. Yet, Mesoamerica remained politically fragmented throughout the entire pre-hispanic era and at no point was it integrated under a single government. Long-term political fragmentation of this area resulted from contingent cross-scale interaction of world-systems processes at the macroregional scale and collective action processes at the regional scale. In this article, I summarize the long-term patterns in these two processes, their cross-scale interaction, and their impact on individual regions from the Formative through the Postclassic. For those readers not familiar with Mesoamerica, I begin by laying out the basic environmental, geographical, cultural, and chronological features of this impressive civilization. I then provide a brief theoretical review of world-systems theory and collective action theory as they apply to premodern states and civilizations. Finally, I trace the cross-scale interaction of these processes for the most important chronological blocks in the Mesoamerican cultural sequence (Early Formative, Classic, Late Postclassic).

Background

Geographically, Mesoamerica extends from the southern boundaries of Mexico's northern desert region to Central America. This area covers approximately 950 000 km^2 and is divided into seven major geographical subareas (**Figure 1**; **Table 1**). Historically, human occupation of these subareas is divided among archaeological 'periods' based primarily on changing patterns in subsidence strategies and political complexity (see **Figure 2**; **Table 2** for information on key processes during each period). The character of Mesoamerican civilization reached its fullest expression during the Late Postclassic, a period known through a combination of archaeology and history. The key features of Mesoamerica during this period were intensive agriculture, craft specialization, markets, sedentism, urbanism, states, writing, religion, calendar, mathematics, social organization, and monumental architecture (see Blanton et al., 1999: Chapter 1).

Importantly, the degree of intensive agriculture and craft specialization were made possible by the evolution of complex marketing systems (Blanton, 1996; Blanton et al., 2005; Masson and Freidel, 2012). Ancient Mesoamericans bought and sold goods and services in a vast array of different types of markets. The major market systems operated on a 5-day market cycle and secondary markets met every 20 days. Market transactions were conducted with both commodity money and through in-kind payments. The primary commodity monies were cacao beans, cotton quilts, and feathers covered in gold dust (Smith, 2003, pp. 115–117). Together intensive production and markets supplied Mesoamerica's cities with foodstuffs, goods, and services.

Mesoamerican cities ranged in size from a few thousands to hundreds of thousands of inhabitants and could be either sparsely occupied (5–20 people/ha) to densely packed (100–200 people/ha). In many cases, these cities were several times larger than other settlements in their hinterlands, indicating that urban centers monopolized economic, political, ideology, and social power. Monumental architecture (pyramids, palaces, plazas) was generally located at the center of cities. In some cases, the state engaged in public planning and constructed (paved) roads (organized on a grid), canals, and bridges, as well as public architecture at the centers of state-administered wards (Fargher and Blanton, 2007). In other cases, political officials (usually kings) planned only monumental architecture at the center and the rest of the city exhibited chaotic, mazelike urban landscapes (e.g., Tikal (Carr and Hazard, 1961)).

Figure 1 Map of Mesoamerica showing subareas (boundaries marked by solid line, subareas by dashed line).

Table 1 Geography and environment of Mesoamerica

Geographical subarea	*Area (km^2)*	*Geography*	*Climate*	*Rainfall (mm)*
West Mexico	200 000	Mountainous with valleys and basins, coasts	Semiarid – subhumid	250–950 (>2000 along coasts)
Central Mexico	68 000	Mountainous with valleys and basins	Semiarid – subhumid	250–950
Gulf Coast	90 000	Littoral backed by mountains	Humid	>2000
Oaxaca	90 000	Mountainous with valleys and basins, coasts	Semiarid – subhumid	250–950 (>2000 along coasts)
Mixe-Zoque	25 000	Coastal plain and piedmont mountain zones	Humid	>2000
Maya area	340 000	Low land plains, coasts, plateaus, and mountains	Semiarid – Humid	250–4000
Southeastern periphery	129 000	Mountains and coasts	Humid	>2000

Finally, cities and their hinterlands were governed by a vast array of states built around diverse political strategies. Some states were small, covering 50 sq.km, whereas others were massive covering tens of thousands of square kilometers. Kings ruled some states (e.g., Maya, Mixtec) and councils consisting of both nobles and commoners governed others (e.g., Tlaxcallan, Teotihuacan) (Blanton et al., 1996; Fargher and Blanton, 2007; Fargher et al., 2011; Sharer, 1994). From ethnohistory, we know some indigenous names for states (e.g., *altepetl* in the Basin of Mexico; *tlahtocayotl* in Puebla; *ñuu* in the Mixteca Alta; *quiche* in the Valley of Oaxaca) (Fargher et al., 2011; Oudijk, 2002). In some cases, these states conquered neighboring states to create empires, e.g., the Aztec Triple Alliance (Chase et al., 2009).

Explaining the Long-Term Evolution of Ancient Mesoamerican Civilization

Collective Action Theory

The long-term history of Mesoamerican civilization allows for the comparative examination of how different revenue (state financial) strategies shaped political organization and the consumption of resources. Revenue strategies may be grouped as either 'internal' (taxes on agricultural production, ordinary market transactions, corvée, etc., paid by free citizens) or 'external' (state ownership of mines, slaves, agricultural estates, animal herds, or control of international trade). States financed through internal revenues depend on taxpayers for their revenues and, thus, must convince them to pay their taxes. They do this by offering taxpayers voice (participation in the political process) and public goods (e.g., public planning, public security, water and sanitation services, road and bridge construction and maintenance, social security, etc.), as well as bureaucratizing public administration (to limit corruption, punish tax evaders, and distribute public goods) and limiting the degree to which governors (kings, presidents, etc.) can use public funds for their personal gratification, which results in highly collective states (see Blanton and Fargher, 2008). Conversely, states funded through external financing do not need to persuade citizens to pay taxes; and, consequently, these states tend not to offer public goods and voice nor bureaucratize, and are, thus, low in collectivity. The governors of these states build social networks to achieve their political goals by

distributing exotic and luxurious gifts, hosting elaborate and exclusive feasts, and gifting the right to extract revenues from certain settlements or regions to powerful clients.

Integrating World Systems and Collective Action

Cross-cultural research indicates that principals configured their response to wealth generated by international trade depending on their overall revenue strategy. Most commonly, governing officials sought to monopolize or control long-distance exchange and use this revenue to build networks of power (see Blanton and Fargher, 2008). However in a few cases, rulers rejected control over international trade as a revenue source in order to curb or limit its impact on politics and power. In order to do this, governing officials attempted either to squash long-distance exchange or direct goods acquired through it to collective consumption in public rites and feasts and/or into markets open to all citizens. Concurrently, they developed political structures that effectively controlled malfeasance and punished corrupt political officials,

including rulers. Cross-culturally, the promotion of rule by council or multiple principals (e.g., republics and democracies) seems to be a favored pathway for controlling the agency of governing officials, but others exist (see Blanton and Fargher, 2008).

Thus, following from these ideas, I (1) explore the ways that governing officials confronted the social problems created by international trade during the Early Formative, Classic, and Late Postclassic Mesoamerica; and (2) describe the ways that these responses affected the organization of the state. In general, Mesoamerican states that relied heavily on long-distance exchange to fund political objectives were fragmented, contentious, dangerous, and oppressive, with few public goods or opportunities for citizens to express their voice (i.e., low in collectivity); alternatively, states that focused on internal revenues and rejected monopolies on international trade by rulers were inclusive and ordered with extensive public goods, opportunities for voice, and bureaucratization of public administration (i.e., high in collectivity).

Case I: Early Formative (3150–2900 Years Ago)

During the latter part of the Early Formative Period, the first major phase of world-systems integration took shape in Mesoamerica. This period is marked by interregional exchange of prestige goods, like baby-face figurines, jade, pottery, and iron-ore, the development of an international style ('Olmec'), and shared ideological and religious orientations across much of Mesoamerica, but especially in Central Mexico, Oaxaca, and on the Gulf Coast (Figure 3). The increased interregional interaction produced notable impacts at the regional- and site-scale. However, the impact of this heightened exchanged varied from region to region.

San Lorenzo

Extant evidence strongly indicates that political power at San Lorenzo was built around external revenue sources. Evidence of strategies to build cooperation between rulers and constituents and encourage compliance with revenue demands is absent. High-status individuals sought to control or monopolize key prestige goods and ideological sources of power. Coercion may also have been employed to acquire wealth, foodstuffs, and dependent laborers (Clark, 1997). Revenues derived from these monopolies were poured into monumental art, elaborate residences, and personal adornment. One of these residences was a 12-m-long apsidal structure constructed atop a 2-m-high platform that covered 3750 m^2 (Cyphers, 1996). A second excavated residence may have been even more impressive with a 3.5-m-tall central basalt column, carved stone step covers, stone benches, plastered and painted walls, and a stone aqueduct that brought water to the house from a lagoon on the plateau (by comparison low-status individuals resided in simple wattle-and-daub dwellings) (Cyphers, 1996). Moreover, carved stone depictions of high-status individuals show them in elaborate dress decorated with jewelry, scepters, and headdresses (Grove, 1997). Monumental art focused on demonstrating control over access to the supernatural and on the personalized images of important individuals (Clark, 1997; Grove, 1997). However, high-status individuals did not invest in monumental public construction (mounds or pyramids) or in elaborate tombs either (Grove, 1997).

All of these data point to the fact that power was highly personalized and institutional structures or infrastructure that could control the agency of political officials, distribute public goods, accommodate voice, monitor taxpayer compliance, and justly collect taxes were absent. Accordingly, evidence of even the most basic public goods is absent during the Early Formative from San Lorenzo. Furthermore, structures that would have allowed for the transgenerational transference of power were also absent. As a result, the political arena was highly competitive and instability was pervasive. Lineages were probably only able to maintain power for a generation or two at best, and power most likely shifted frequently among lineages.

Figure 3 Map of Mesoamerica during Early Formative (boundaries marked by solid line, size of circle corresponds with relative population size).

San José Mogote

The political situation at this site was very different than the situation at San Lorenzo. It appears that at San José Mogote, personal wealth acquired through control over prestige goods was not used to gain political power. A large number of households engaged in the production of different prestige goods, including ornaments using shell from the Pacific and Gulf coasts, chert bifaces, and magnetite mirrors and traded for mica, jade beads, serpentine, and carved pottery (Marcus and Flannery, 1996). The only prestige good that seems to have been tightly controlled was magnetite mirrors, but this control did not provide households with access to more or better exotic goods nor to political power (Marcus and Flannery, 1996). Thus, despite the exchange and consumption of prestige goods, marked social inequality in houses and burials was limited and residences comparable to the high-status dwellings at San Lorenzo were absent (Marcus and Flannery, 1996). Apparently, the residents of San José Mogote developed an inclusive or collective political apparatus that effectively separated wealth from political power. Blanton et al. (1999) suggested that this was accomplished by a concept of dual opposition between male descent groups, one associated with earth and the other with sky. Instead of pouring revenues into extravagant houses, they were used to erect a public building. During the late Early Formative, the residents of San José Mogote along with residents from neighboring sites constructed a two-tier stone-faced platform 3.5-m high (Marcus and Flannery, 1996). This edifice functioned as a staging area for inclusive community-wide public rituals, large-scale feasting, and meetings among the site's household heads to resolve disputes and collect foodstuffs for rituals and other public functions, among other things.

Paso de la Amada

Although partially contemporaneous with San Lorenzo and San José Mogote, the residents of this site did not participate in the 'Olmec' exchange network; thus, Early Horizon markers have not been recovered from this site. Instead wealth and power were demonstrated by access to labor for the construction of large structures raised on platforms, which functioned as both dwellings and ritual/public spaces (Lesure, 1997, 2011; Lesure and Blake, 2002). These structures were surrounded by small residences, forming clusters distributed across the site. By the middle part of the occupation, construction at all of the large structures ceased except at Mound 6, which was reconstructed several times over a period of about 200 years and became the largest structure at the site (Lesure, 1997, 2011). Apart from the large and small dwellings there is no other architecture at the site except a single ballcourt (Lesure and Blake, 2002), but, it is not clearly attached to any of the large structures (Lesure, 2011). Evidence of plazas or other public spaces is debatable (see descriptions in Lesure, 2011).

Surprisingly, burials and artifact distributions indicate that there were only minor differences in wealth among the residents of the large and small dwellings (Lesure and Blake, 2002). Exotic items were comparatively infrequent in all contexts, but regularly distributed among households and burials. None of the burials or houses showed significant concentrations of items that set them apart as higher status (Lesure and Blake, 2002). The only artifact category that differs in distribution is the large hollow ceramic statue, which probably had a ritual function and has only been recovered from large structures (Lesure and Blake, 2002).

These data indicate an emphasis on internal revenue, specifically labor or corvée supplied by independent (free) households. This labor was deployed in the construction of the large houses but was not used to produce prestige goods for an emergent 'elite.' That is to say, leaders did not directly control labor and could not use it to increase their personal wealth and attract clients or coerce independent individuals. So what motivated the residents of small dwellings to participate in the construction of large dwellings? Lesure and Blake (2002) suggest that the individuals who participated in the construction of large houses may have had a claim on their use. They probably were entitled to participate in events such as dances, drinking events, rituals, social gatherings, political meetings, and gambling that occurred within the structures. However, their participation in construction was voluntary and probably based on an assessment of the potential benefits as well as an evaluation of the degree to which the leader upheld his or her end of the bargain on previous occasions. Where the benefits were well supplied and the leader did not exploit his position, individuals probably were willing to participate in future construction events. However, where the leader did not uphold his end of the bargain, individuals would refuse to cooperate or even shift their allegiance to other leaders.

Such a framework, based on a theory of contingent cooperation (that is to say, individuals choosing to participate or refusing to do so based on a case-by-case consideration of the costs and benefits of participation), fits well with the archaeological record. Some clusters never constructed a large dwelling (they failed to cooperate), other large dwellings were constructed, used, rebuilt, then suddenly abandoned, and sometime later reoccupied or remodeled (contingent cooperation). However, in the case of one cluster, cooperation was sustained over an extended period of time and the large dwelling and its platform (Mound 6) were rebuilt several times. During each construction phase, the dwelling was successively enlarged probably indicating that the size of the cooperating group expanded over time. Then suddenly cooperation failed and the dwelling was abandoned.

Thus, the political aspirations of Paso de la Amada leaders were held in check by contingent cooperation. My systematic cross-cultural research indicates that leaders in these contexts have much prestige and influence but little authority (power over others) (see also Lesure and Blake, 2002). Political decisions are consensus-based and community or group members are free to cooperate or to defect. In these situations, leaders may claim hereditary rights and live in larger (but not usually better made) dwellings, but any attempt to divert resources for personal gain or engage in coercion are counteracted by defection or exit (group members refuse to cooperate or join other groups). Conversely, leaders are expected to continuously supply members with services and the use of their dwellings as semipublic space in order to maintain the cooperation of group members.

Case II: Classic Period (1750–1250 Years Ago)

During the Terminal Formative (2150–1750 years ago) (Figure 4), collectivity reached a noir. Across Mesoamerica, political strategies generally shifted toward coercion, exclusion, and exploitation by emergent elites. In the Valley of Oaxaca, the highly collective or corporate Monte Albán state shifted toward a prestige goods economy (Elson and Sherman, 2007; Kowalewski et al., 1989). On the Pacific Coast of Oaxaca, the highly collective polity at Rio Viejo went into decline (Joyce and Barber, n.d.). At Teotihuacan, an emergent elite began to materialize its control over resources in the form of elaborate tombs, one under the Pyramid of the Feathered Serpent and another 'shaftlike' tomb constructed on the future site of the Pyramid of the Sun (Cowgill, 2008; Sugiyama, 2005; Sugiyama et al., 2013.) In West Mexico, high-status individuals constructed spectacular shaft tombs and filled them with massive amounts of funerary offerings (Pollard, 1997). Finally, the Maya of the Central Peten shifted toward an emphasis on personal power expressed in individualized portraiture of rulers, royal genealogies, and elaborate tombs (Sharer, 1994). Such patterns in the archaeological record suggest an underlying, pan-Mesoamerican, shift toward external revenues, a decline in cooperation between constituents and principals, and a corresponding increase in the ability of principals to behave despotically. Such was the political situation at the outset of the Classic Period when a startling shift in political policy took root in the western half of Mesoamerica.

Teotihuacan

Principals at Teotihuacan apparently shifted financial policy back toward internal revenues sources at the beginning of the Classic Period (Figure 5), promoting especially agriculture production and craft specialization, and curtailing the use of prestige goods in the political arena. Accordingly, they limited exchange in prestige goods and directed exotic goods into public rituals and offerings and away from personalized or individualized consumption. Thus, a growing number of scientists are coming to the conclusion that principal authority at Teotihuacan was vested in a ruling council (Blanton et al., 1996; Cowgill, 1997; Millon, 1976). This council apparently focused on providing public goods and voice to Teotihuacanos in exchange for compliance with taxation paid in kind and through corvée. Specifically, it provided public spaces for citizens to assemble, express their voice, and participate in mass rituals and feasts, as well as a highly planned urban landscape that included (Cowgill, 1997; Millon, 1973) the following:

- the construction of the massive and accessible pyramids and plazas, roads, and drains;
- the organization of the city on an orthogonal grid centered on the street of the dead (a massive avenue that extended 5 km) and a massive east – west avenue that intersected the former avenue at the geographical center of the city, with secondary streets and alleys connected to them;
- the redirection of the San Juan River, which runs through the city; and
- the relocation of residents in more than 2000 highly standardized, internally complex, multifamily, masonry residential compounds, which were arranged in comparatively standardized neighborhoods or wards that may have in turn been clustered in standardized administrative districts (Gómez-Chávez, 2012).

Social stratification, as well as wealth and power differences, was strongly muted following political reorganization at the onset of the Classic. There is not a single royal interment in any of the major monumental architectural complexes at this time and 'elite' or 'royal' burials dating to the Formative were systematically looted (see Sugiyama and Cabrera Castro, 2007; Sugiyama et al., 2013). Teotihuacanos were buried under the floors of administrative complexes or the central patios of their residential compounds with relatively few offerings

Figure 4 Map of Mesoamerica during the Late-Terminal Formative (boundaries marked by solid line, size of circle corresponds with relative population size).

Figure 5 Map of Mesoamerica during the Classic (boundaries marked by solid line, size of circle corresponds with relative population size).

(Gómez-Chávez, 2012). The most elaborate and complex objects consisting of composites of imported materials were used in state rituals and buried in the numerous temples that dot the city (Sugiyama and Cabrera Castro, 2007; Sugiyama et al., 2013). Named lineages and clear images of rulers do not appear in public contexts (Blanton et al., 1996). Instead, public murals and carved stone depict processions with large numbers of individuals, individuals wearing masks, and apparel hidden by feathers, which induces a sense of facelessness and collectivity (Blanton et al., 1996). Finally, not a single residence stands out as exceptionally large and opulent (a 'royal' palace) (Cowgill, 1997).

Monte Albán

In the Valley of Oaxaca (**Figure 5**), research indicates that the Monte Albán state shifted toward collectivity in the Early Classic Period (1750–1450 years ago). Revenue strategies appear to have shifted from control over the production and distribution of prestige goods (especially cream-ware pottery) to agricultural taxes and corvée (Kowalewski et al., 1989). Coupled with this change, political architects at Monte Albán focused on the bureaucratization of public administration (Fargher, n.d.). These processes unfolded as follows. First, key centers of provincial power during the Terminal Formative, which were centered on elite residential, funerary, and ritual complexes, were abandoned and replaced by new 'bureaucratic' centers that were located in previously unoccupied sites and positioned to form a continuous network of regularly spaced centers extending out from Monte Albán (Kowalewski et al., 1989). Second, these new centers focused on open and accessible plazas (Blanton, 1989). Adjacent to these plazas, the state constructed specialized (nonresidential) administrative buildings (see Blanton, 1989; Feinman and Nicholas, 2011). Moreover, the organization and orientation of these administrative complexes were highly uniform across the entire valley indicating their construction was directed by the state (Blanton, 1989). The officials that occupied these structures were 'faceless' and did not claim these structures as personal property (Feinman and Nicholas, 2011). Thus, it appears that public officials (probably sent from other localities) and not local 'rulers' or chiefs administered these centers and their immediate hinterlands. Finally, a similar architectural pattern was used to reorganize the city of Monte Albán into administrative wards where each ward was centered on a public plaza-mound complex (Blanton, 1978).

The outcome of bureaucratization was twofold. First, the design of these new centers placed public plazas (which functioned, among other things, as marketplaces in pre-Hispanic Mesoamerica) under the administration of the state, allowing officials to maintain market security and ensure just and equitable exchange (Kowalewski et al., 1989). Second, it enhanced the ability of the state to provide public security within the valley. Following these political chances, many households migrated to the valley floor and lived in dispersed, unprotected settlements, which indicates that the state was protecting rural peasants from raiding and banditry (Kowalewski et al., 1989).

In keeping with the expectations from collective action theory, data from Monte Albán indicate constraints on the ruler's control of material and ideological resources along with the possibility of political structures that encouraged power sharing. Although high-status residences and tombs (which were constructed under houses) were more elaborate than those of ordinary households, they are comparable in scale and wealth to 'royal' installations (Joyce, 2010; Marcus and Flannery, 1996). Importantly, royal tombs were not placed in massive pyramids and intact tomb offerings suggest relatively modest displays as compared with Classic Maya tombs. In more public contexts, personalized images of rulers are comparatively rare, lengthy royal genealogies are nonexistent and carved stone monuments were frequently recycled (Joyce, 2010). These data suggest frequent shifting of the highest political office at Monte Albán among unrelated

individuals or lineages, but these shifts occurred in the absence of internal strife or civil wars. Additionally, a carved stone monument shows a king surrounded by a group of high-status individuals who may have shared power with the ruler (Joyce, 2010). Taken as a body, these data hint at the possibility that an advisor council shared power with the king and may have even intervened in succession processes and elected rulers from a group of candidates that included individuals from different lineages.

Tikal

Tikal contrasts sharply with Teotihuacan and Monte Albán. At this site, external revenue strategies dominated during the Early Classic Period (1750–1450 years ago) (**Figure 5**). Rulers there focused on the accumulation and use of personal wealth to attract and maintain clients (Blanton et al., 1996). Coercion, involving defeat and subjugation of competing rulers at neighboring sites, was also used to acquire revenues and to control recalcitrant clients (Sharer, 1994). The city's location between two river systems, one flowing to the Gulf of Mexico and the other to the Caribbean Sea, allowed it to control the flow of valuables across the region (Sharer, 1994). Rulers may also have controlled water by capturing rainfall in massive reservoirs, both emphasizing their symbolic power and allowing for the irrigation of nearby agricultural fields that were probably claimed as the personal property of the ruler (Scarborough, 1998). Tikal's rulers monopolized ideological resources by claiming special descent, personal links with deities, and direct control over sacred monuments like the city's massive pyramids. On carved stone, Tikal's early kings claimed descent from an individual who originated in a place that epigraphers believe is Teotihuacan (Sharer, 1994).

Revenues accruing from monopolies on long-distance exchange and ideological resources, as well as on the land fed by royal reservoirs, were plowed into conspicuous consumption. Kings and the high nobility were depicted on carved stone, polychrome pots, and murals dressed in elaborate headdresses and fine jewelry and clutching symbols of power (e.g., Sharer, 1994). They are shown seated on thrones, which have been recovered archaeologically, and mats. They used fancy polychrome pottery, jade, objects made of other types of green rock, elaborate shell artifacts, highly complex chert eccentrics, and green obsidian (from Central Mexico) (Sharer, 1994). They lived in beautiful, elaborate, and massive palaces. The massive Central Acropolis at Tikal was home to kings over many generations. Upon their death, kings and queens were interred in elaborate tombs buried under personalized funerary pyramids.

Although Tikal was the most important state in the Central Maya Area during the Early Classic it did not control the entire Maya Area. Instead, the landscape of the Central Maya Area was highly fragmented and states fought with one another to gain prestige, which was necessary for recruiting and maintaining client states. The principal figures in this bloody, jewel-encrusted drama were Tikal, Calakmul, Caracol, Copán, Palenque, Rio Bec, and Altar de Sacrificios, to name just a few (Sharer, 1994).

Epiclassic – Early Postclassic (1250–750 Years Ago)

Around 1250 years ago, a marked change in political policy occurred and the major Classic Period states went into decline (**Figure 6**). The following Epiclassic Period (1250–1050 years) in many ways marked a return to strategies that were dominant during the Terminal Formative. Across much of Mesoamerica, principals emphasized external revenue strategies based on monopolies over ideological and economic resources (especially long-distance exchange) as well as coercion. In Central Mexico, Teotihuacan's introverted and complicated style gave way to unrestrained audacious displays of wealth and

Figure 6 Map of Mesoamerica during the Epiclassic-Early Postclassic (boundaries marked by solid line, size of circle corresponds with relative population size).

personal power. For example, kings built massive and luxurious palaces at Xochitecatl, Cacaxtla, and Xochicalco (Hirth, 2000; Lombardo de Ruiz et al., 1986; Santana et al., 1990; Serra Puche, 1998). The palace on the top of Cerro Cacaxtla is truly exceptional. Here, resplendent murals are preserved that depict war, fertility, Venus figures, and possibly rulers or other high-status individuals linked with supernatural forces (e.g., a feathered serpent and a jaguar) (Stuart and Ferorelli, 1992). In the Valley of Oaxaca, the bureaucrats of the Monte Albán state began claiming individualized personal power. They began enclosing the public plazas, making them private, constructing impressive subfloor tombs under formerly administrative building, and carving stone stalæ showing their personal genealogies and marriages (Fargher, n.d.; Feinman and Nicholas, 2011). The provincial elites that had been suppressed during the Classic Period apparently reemerged, reclaiming and rebuilding their Terminal Formative centers of power with palaces and tombs (Fargher, n.d.). In the Maya lowlands, military competition and prestige good consumption spiked (Sharer, 1994). The major regional powers (e.g., Tikal, Calakmul, Caracol) collapsed and the political landscape fragmented further. For a brief period during the Early Postclassic (1050–750 years), principals at Tula (Central Mexico) and Chichen Itza (Northern Yucatan) may have shifted political policy back toward collectivity to some degree (Blanton et al., 1996). But much work still needs to be done to understand the nature of the changes.

Case III: Late Postclassic (750–500 Years Ago)

The final period in the pre-Hispanic sequence began about 800 years ago and ended with Spanish conquest in AD 1521 (**Figure 7**). In Central Mexico, West Mexico, and Oaxaca, this period was marked by long-term population growth, increasing commercialization, and the gradual political consolidation of three major empires: (1) the Aztec empire (Aztec Triple Alliance), which controlled large parts of Central Mexico, the Gulf Coast, and Oaxaca, as well as the Pacific Coast of Chiapas and small polities on the Coast of West Mexico in modern Michoacan and Guerrero; (2) the Tarascan Empire which controlled much of West Mexico; and (3) the Tututepec Empire which controlled the Pacific Coast of Oaxaca extending from the Isthmus of Tehuantepec into Guerrero (Berdan et al., 1996; Joyce et al., 2004; Pollard, 1982). Overall, Mesoamerica reached its highest degree of cultural and economic integration during this period (Blanton et al., 1999).

Aztec Triple Alliance

Following the collapse of Teotihuacan, the Basin's population dispersed and eventually concentrated around a large number of competitive city-states (Sanders et al., 1979; Smith, 2008). Then around 650 years ago, the political and demographic landscape shifted markedly and the political landscape consolidated around three major blocks, which were ultimately united under a single capital by the ruler (or *tlatoani*) of Azcapotzalco (van Zantwijk, 1985). However, around 1426 the ruler of Azcapotzalco died and a succession dispute erupted. During the ensuring war, in 1427 or 1428, three Mexica-Tenochca relatives (Itzcoatl, Motecuhzoma, and Tlacaelel) and their Acolhua cousin (Nezahualcoyotl) conspired to take control of Tenochtitlan, Texcoco, and then, with the help of Tlacopan (or Tacuba), the entire Basin of Mexico (Fargher and Blanton, 2007). Over the next 70 years, population growth and commercialization surged under the internal peace and imperial wealth brought by the Aztec Triple Alliance (Blanton et al., 2005; Sanders et al., 1979). Tenochtitlan-Tlatelolco became the largest city in the history of Mesoamerica, with a population of 150 000–200 000 people (Sanders et al., 1979).

Figure 7 Map of Mesoamerica during the Late Postclassic (boundaries marked by solid line, size of circle corresponds with relative population size).

The Aztec Triple Alliance pursed a mixed revenue strategy. The principal internal revenues sources were taxes on ordinary market transactions, which were collected at the numerous marketplaces distributed across the Basin of Mexico, agricultural taxes and corvée on free peasants, and imperial tribute collected by the state (Fargher and Blanton, 2007). External revenues accrued to the principals of the Aztec Triple Alliance through ownership of agricultural estates worked by dependent laborers and laborers attached to their personal residences (Fargher and Blanton, 2007). However, these revenues were relatively minor compared to internal revenues because free peasants held the majority of agricultural land in the Basin of Mexico.

In order to encourage compliance with revenue demands, the Aztec Triple Alliance implemented bureaucratization, distributed public goods, accommodated voice, and placed limits on the agency of principals (Fargher and Blanton, 2007). First, the Aztec Triple Alliance was governed by a council called the Tlatocan, which consisted of the *tlatoani* (ruler) of Tenochtitlan, the *tlatoani* of Texcoco, the *tlatoani* of Tacuba, the *cihuacoatl* (coruler) of Tenochtitlan, and four prime ministers (the four prime ministers of the Triple Alliance always included at least one peasant). The tlatoani of Tenochtitlan was the most important and influence individual member of the Aztec government and carried the title of hueyi tlatoani (literally great speaker). This council had the power to monitor and punish every single political official in the government including the *hueyi tlatoani* and exercised this power. Second, low-level administration was divided into a series of bureaus (e.g., tax collection, policing and justice, military direction, and a 'complaints' department). Officials were selected in part on merit and commoners could enter bureaucratic service; they were trained at special schools; they were carefully monitored and corrupt officials were punished; and they were paid an in-kind salary drawn from lands assigned to each office. Third, the Triple Alliance provided extensive public goods, especially within the capital (Tenochtitlan) but across the territory of the empire as well (Fargher and Blanton, 2007). The primary public goods were road and bridge maintenance, aqueducts, irrigation and drainage canals, dykes, public parks, plazas, redistribution during famines, and public security. Finally, the architects of the Aztec empire created a court system with a precise appeal hierarchy that treated all members of the Aztec society as equals regardless of social status ('judicial equality').

Mixteca Alta

During the late Postclassic, the Mixteca Alta of Oaxaca was divided among many competing petty kingdoms or states each ruled by a royal lineage and a small hereditary nobility that was probably closely related to the ruling line (Fargher et al., 2011; **Figure 7**). In contrast to the Aztec Triple Alliance, revenue sources were strongly external. The key revenue sources were monopolies over irrigated agricultural lands, dependent serflike laborers, and long-distance exchange in prestige goods (Fargher et al., 2011). Rulers used these revenues to build lavish palaces and adorned themselves with beautiful jewelry. The key durable prestige goods included resplendent pottery painted with images of the vessels' owners and supernatural themes, gold, silver, gold–silver alloys, copper, marine shell objects, rock crystal, intricately carved bone, and polished obsidian jewelry (Caso and Borbolla, 1969). Rulers used these goods to attract and maintain networks of clients that carried out their political will. They did this instead of investing in public goods or accommodating taxpayer voice (Fargher et al., 2011). As a result, the Mixteca Alta was riddled by internal strife and violent confrontations among the petty rulers, resulting in low public security.

Tarascan Empire

Finally, the Tarascan Empire centered on the Patzcuaro Basin in Central Michoacan is markedly different than the Aztec Triple Alliance and the petty states of Oaxaca (**Figure 7**). Tarascan revenue policy strongly emphasized external revenues and elite consumption, like the Mixteca Alta, which resulted in low collectivity (summarized from Pollard, 1987). However, unlike highland Oaxaca, the Tarascan state used this strategy to build a highly centralized empire. Centralization was achieved by extensive monopolies over economic and ideological resources. Within the basin, the royal family claimed direct control over vast swaths of high-quality agricultural land, as well as a large number of dependent labors, artisans, and merchants. Merchants who specialized in long-distance exchange worked exclusively for the king, bringing in exotic prestige goods like chocolate, animal skins, feathers, turquoise, gold, silver, slaves, and many other products from the edges of the empire and beyond. However, merchants did not sell any of these items because all of it was owned by the king. The ruler also directly controlled copper mines worked by dependents and collected tribute from workers exploiting other mines. Finally, the king received tribute from conquered polities outside the basin.

The king was the sole receiver and distributor of these revenues. They were used principally to fund consumption on a massive scale by the royal household, state religious ceremonies, and to control the nobility. The king constructed a colossal palace set atop a platform 10 times larger than Motecuhzoma II's palace (Pollard, 1980; Smith, 2003). He also constructed a religious complex consisting of one large and two smaller platforms, which were used to store massive amounts of prestige goods. The remainder of the revenue was gifted to the high nobility, who constructed their residences in a cluster surrounding the royal palace (Pollard, 1980).

Not surprisingly, public goods and bureaucratization were not a high priority of the king. The capital (Tzintzuntzan) is described as an unplanned settlement and no mention is made of roads, aqueducts, or public spaces in written records (Pollard, 1980). The state showed no interest in administering markets (e.g., offering dispute resolution and consumer protection, etc.) and peasant markets were marginalized, operating completely independently of the state-based prestige goods economy (Pollard, 1982). Although the state collected maize and cotton tribute, these products were not redistributed to commoner or peasant households (Pollard, 1982). The degree of bureaucratization appears to have been very low. The chief political officials were part of a hereditary nobility and were tied personally to the king through gift exchanges involving prestige goods, land, and service to the state. The lower level nobility probably was

in turn personally tied to members of the high nobility through similar gift exchanges. Thus, elite status was defined by access to state-produced prestige goods and commoners, except successful warriors, were completely excluded from these exchanges, resulting in clearly divided social classes and stratification (Pollard, 1982; Pollard and Cahue, 1999).

Discussion

The cases described here, while representing only a fraction of Mesoamerica's ancient diversity, illustrate a number of important features. First, the most common pattern in the revenue strategies and political organization in Mesoamerican states were external revenues based on control of or monopolies on interregional prestige goods exchanges. This pattern is logical because control of external revenues is a more cost-effective strategy for principals to employ. Thus, the cases in which principals focused on internal revenues, Teotihuacan, Aztec Triple Alliance, and Monte Albán, stand out. It also appears that collective states based on internal revenues that separated wealth acquired through control of prestige goods from political power were the only ones to influence the entirety of the Mesoamerican world during their apogees (e.g., Teotihuacan, Tenochtitlan). Second, cases where principals were able to fully monopolize prestige goods exchanges at the interregional scale and use the wealth derived from this monopoly to build a centralized and stable political structure were also rare (the Tarascan Empire is the only example). Outside of Mesoamerica, this pattern is rare also. A recent global analysis (Blanton and Fargher, 2008) found only one other case (Egypt), where principals were able to fully monopolize interregional exchange. Thus, this is an exceptionally rare pathway to complexity, probably because such complete monopolies are so difficult (and costly in human lives) to achieve.

The cases described in this article provide important information on the relationship between collectivity and long-distance exchange. Building collective polities in a world economy poses unique challenges for principals. In all of the cases that emphasized internal revenues, principals had to develop a combination of collective strategies that devalued prestige goods and placed controls on political actors to keep them from using prestige goods to disrupt political policy. In the case of Teotihuacan, principals used the hegemonic position of Teotihuacan in the Classic Period Mesoamerica world to constrain the flow of prestige goods and direct it into public consumption locally and into diplomatic arenas outside of the state's territory. Teotihuacan's political architects also developed strong controls on rulers and political officials, which allowed the state to collect and even make large amounts of prestige goods without disrupting collectivity. Monte Albán's principals appear to have capitalized on Teotihuacan's international policy regarding prestige goods to build an internal revenue system. They too appear to have built political structures that separated wealth from power and constrained the agency of the king. Conversely, the Aztec Triple Alliance capitalized on interregional flows of wealth items to stimulate commercialization and, thus, market revenues. Instead of squashing the international economy and the interregional exchange of wealth items, Aztec principals dumped wealth items paid in tribute on the market. This strategy essentially made wealth items available to everyone at comparative low cost (turning them into bulk luxury goods), which effectively killed their value as political currency. At the same time, they built a political structure that effectively controlled the agency of principals and political officials alike, which allowed them to pursue internal revenues.

Thus, these data seam to hint at 'core strategies' in ancient Mesoamerica that are similar to 'core strategies' in the modern world economy. These strategies include the following: (1) strategies to keep wealth generated by international trade out of the political arena; (2) an emphasis on internal revenue strategies; (3) collectivity (bureaucratization and public goods); and (4) controls on the agency of principals so that even if they get a hold of or posses great wealth they cannot use it to act despotically. Conversely, 'periphery strategies' emphasize attempts to monopolize interregional interaction and use the revenue it provides to recruit clients through gifting, conspicuous consumption, and coercion. Moreover, attempts at monopolizing interregional exchange tend to correlate with a politically fragmented landscape and instability (e.g., frequent and violent confrontations among petty rulers competing for power).

Meta-Analysis, History of

David J Roelfs, University of Louisville, Louisville, KY, USA

Abstract

Meta-analysis is a type of systematic literature review through which a researcher can combine the results of existing studies to produce an overall estimate of the magnitude of a statistic such as a mean, correlation, or odds ratio. Meta-analyses are often coupled with meta-regressions, which are multivariate analyses of the effect of between-study differences on the magnitude of the statistic of interest. Developments to meta-analytic and meta-regression methodology are ongoing, with a trend emerging toward using the techniques to examine causal pathways.

Meta-analysis is a quantitative technique through which a researcher can combine the results of methodologically similar studies to produce a single, overarching statistical result.

The term 'meta-analysis' was coined, and the technique largely developed, in the late-1970s by statistician and educational psychologist Gene V. Glass (see Glass, 1976). The impetus for the development of meta-analysis was the lack of statistical power in the psychology experiments of the time. Lacking funds to conduct experiments on a large sample of people, psychologists would opt for small study sizes and, as a result, frequently find that their variables of interest were not statistically significant. By using a technique that allowed for the aggregation of existing research, meta-analysis allowed Glass and his colleagues to examine commonly studied variables with a much higher level of statistical power without incurring substantial financial costs.

Because meta-analysis can only be based on studies using the same empirical measures, it was first adopted by disciplines where studies were most directly replicated. Within the social sciences, the method was first put to use in psychology. In the first 10 years following the creation of formal meta-analysis methods, psychologists (including both educational and noneducational researchers) predominantly used the method to study treatment effectiveness (e.g., psychotherapy), the correlates of academic achievement, or human sex differences. In the next 10 years, psychologists began to use meta-analysis to study the effectiveness of various drug treatments (particularly for depression) and factors related to depression more broadly, while still retaining a focus on human sex difference research. In the third decade, meta-analysis was used in a more concentrated way for the study of all types of mental illness, with studies of depression and schizophrenia dominating the research. Today, psychologists continue to focus on drug therapies and other interventions for the major mental disorders. Over these four decades, the number of meta-analytic studies grew exponentially, from a few dozen in the first decade to several thousand in the most recent 10 years.

The method almost immediately spread outside of the social sciences, through psychiatry, to the medical sciences. Today, the medical sciences are the foremost users of meta-analysis, which has become one of several tools facilitating the ongoing shift toward what is known as 'evidence-based medicine.' While psychologists were the first to conduct meta-analyses and have produced several thousand meta-analyses over the past 40 years, medical researchers have now conducted nearly five times as many meta-analytic studies. In the initial years, medical research focused on many of the same issues as psychologists: psychotherapy, depression, and mental disorders more broadly. After the initial 10 years, however, medical research diverged strongly. Meta-analysis was most heavily used in this period for examining the causes and treatments for breast cancer, high blood pressure, and coronary disease (including heart attacks). These foci continued to dominate meta-analyses in the medical field in the 1990s, though research into other forms of cancer (e.g., lung cancer) also became quite frequent. The most recent 10 years, however, has witnessed a dramatic shift in the uses to which meta-analysis has been put in medicine. Researchers are now heavily focused on the genetic aspect of disease, including studies of genetic predisposition and genetic polymorphism. Research into cancer and the other major diseases of the Western world continues to be a major focus as well.

Among the social sciences, with the exception of psychology, meta-analysis remains a much more novel approach. Though early examples of meta-analyses can be found in almost any social science field, its adoption has been episodic and relatively slow. Within the social sciences, psychologists, demographers, and criminologists are the most frequent users of the method. Demographers have most often used meta-analysis techniques to study the social correlates of health (such work is most often published in epidemiology journals). This work differs from that of the medicine field in which the topics studied do not readily translate into treatment recommendations. Instead, demographers have focused most heavily on determining which subpopulations are most at risk. Criminologists have been most interested in using meta-analysis for the study of the risk factors leading to criminal behavior, including environmental (e.g., social upbringing), behavioral (e.g., drug use), and psychological determinants of criminal careers (including recidivism).

Economists, sociologists, education researchers (excluding educational psychology), and anthropologists employ meta-analysis to a small degree, while meta-analytic studies are almost unheard of in communications, geography, history, or political science. It is difficult to discern trends in the uses to which meta-analytic methods have been put within these social science fields. First, the number of meta-analyses within each discipline is small and therefore does not contain dominant

 http://dx.doi.org/10.1016/B978-0-08-097086-8.03223-2

clusters of research topics. Second, the diversity of research topics is much greater than in disciplines such as psychology and medicine. In the social sciences, it is actually quite rare to see two or more meta-analyses on closely related topics.

In the balance of this article, I will review the methodological trajectory of meta-analysis and provide resources related to conducting this type of study (and the related technique known as meta-regression). I will begin by providing an expanded definition and description of meta-analysis. I will then turn to a description of several key methodological issues and subsequent analytical refinements that have driven changes in the way meta-analysis is done. Finally, I will argue that the future direction of meta-analysis lies with meta-regression.

The Logic Behind Meta-Analysis

Meta-analysis, in its most basic form, is analogous to calculating an overall mean from a series of two or more subgroup means. This method for calculating the overall mean is advantageous as it does not require access to the original, individual-level data from which the subgroup means were calculated. Instead, as the example equation below shows, one can derive an overall mean ($\bar{x}_{\text{overall}}$) knowing only the subgroup means ($\bar{x}_i$) and their respective sample sizes (n_i):

$$\bar{x}_{\text{overall}} = \frac{\sum(n_i\bar{x}_i)}{\sum n_i}$$

The data required for a meta-analysis consist of *effect estimates* and their associated standard errors, both of which are obtained from a comprehensive sample of available research studies. Effect estimates can take the form of means, regression coefficients from any type of generalized linear model (e.g., partial slopes from ordinary least-squares regression, log odds from logistic regression, logged rate ratios from Poisson regression, log hazard ratios from proportional hazards regression, etc.), and other similar statistics. Generally, the type of effect estimate chosen follows a normal distribution under the Central Limit Theorem, which excludes using meta-analysis for Chi-square statistics or F statistics. Correlations can be subjected to meta-analysis so long as they are transformed using Fisher's Z transformation. The standard errors of the effect estimates are used to calculate *inverse variance weights* (w_i), where $w_i = 1/se^2$. Regardless of which type of effect estimate statistic one will use, meta-analysis requires that the same statistic be available for all the studies one wishes to combine and that this statistic is based on the same variable (in the case where the effect estimate is a mean) or pair of independent and dependent variables (in the case where the effect estimate is a regression coefficient).

The basic results from the analysis of meta-analytic data are a weighted average effect estimate and a standard error for this weighted average. The weighted average effect estimate ($\overline{ES}$) is calculated using the individual effect estimates (ES_i) and their corresponding inverse variance weights (w_i) using the equation below.

$$\overline{ES} = \frac{\sum(w_i ES_i)}{\sum w_i}$$

The standard error of the mean effect estimate equals the inverse of the sum of the weights ($se_{\overline{ES}} = 1/\sum w_i$). One can use this standard error to calculate the corresponding confidence interval and derive a *p*-value from a hypothesis test for whether the weighted average effect estimate equals zero.

Meta-Analysis and Systematic Literature Reviews

Meta-analysis is a quantitative form of *systematic literature review* as it is based on an attempt to identify and analyze the population of research studies examining a specific variable or association between a specific independent–dependent variable pair. Though every meta-analysis begins with a systematic literature search, the idea of a specific systematic review methodology lagged the development of the meta-analysis statistical procedure itself. Initially, researchers conducting a meta-analysis would likely have given little consideration to the literature review component because, as experts in their respective subfields, they felt aware of the relevant research from the outset.

Subsequent studies have shown there are inherent difficulties in assembling a comprehensive, representative sample of a particular body of research, much less in locating an entire population of studies. The most thorough reviews are based on a multifaceted, multistage literature search. Expertise in one's chosen subfield remains a critical component, as does competency in searching scholarly databases and consulting with other experts in one's field. However, major obstacles inherent in the literature itself affect the search process. First, *publication bias* exists when relevant studies are not made publicly available (e.g., proprietary studies by private companies, which are not published; the tendency to delay or forego publication when one's research that does not find a statistically significant effect for a key variable – the *file drawer effect*). Second, *search bias* exists due to the inconsistencies between researchers, journals, and disciplines in the way research is indexed and reported. Researchers remain responsible for identifying the keywords that will be associated with a particular study; so simple differences in the vocabulary used can hamper the search effort. Furthermore, since one's keywords reflect only the focal concepts in a study, it is difficult for others to determine all of the variables present (the focal variable in a meta-analysis may only be a control variable in some primary studies). Systematic literature reviews are therefore, in practice, based upon samples of relevant studies rather than the population. The question is not whether one has missed a relevant study, but whether one has systematically missed relevant studies.

The first graphical and statistical methods to help detect the presence and magnitude of search and publication bias were developed by Egger and Davey-Smith (1998). The first tool developed for this purpose, known as a *funnel plot* (see Figure 1), is a graph of the values of the effect estimates (*x*-axis) against some measure of the weight the effect estimate had in the meta-analysis (*y*-axis; this is most often either the sample size or the inverse variance weight). If no search or publication bias is present the graph will be symmetric and funnel-shaped, with very little variation in the values of the effect estimates for studies with large weights and greater variation in the effect

Figure 1 Example funnel plot.

estimates for studies with small weights. A lack of left–right symmetry in the funnel plot indicates that a certain class of studies has been undersampled. For example, a funnel plot that is skewed left indicates that small studies with relatively high effect estimate values have been missed.

The statistical test for publication and search bias consists of a weighted ordinary least-squares regression, with the inverse variance weight used in the meta-analysis serving as the regression weight, the effect estimate divided by its standard error serving as the dependent variable, and the inverse of the standard error of the effect estimate serving as the sole independent variable. The intercept/constant from the resulting model will be significantly different from the null value (zero) if publication and/or search bias are present in the data.

The Egger and Davey-Smith method of detecting funnel-plot asymmetry works best when the effect estimates come from relatively homogeneous study samples. When this is not the case, alternative tests may perform better. Of particular importance when using event-history (survival analysis) data is the test proposed by Peters et al. (2006), which is also based on a weighted least-squares regression. The weight for the regression is calculated using information on the numbers in the sample experiencing the event of interest (denoted as n_{event}) and the number not experiencing the event (denoted as $n_{\text{no event}}$) using the following equation:

$$\text{regression weight} = \frac{1}{(1/n_{\text{event}}) + (1/n_{\text{no event}})}$$

The dependent variable in the regression is the log of the effect estimate (e.g., log odds, log hazard), with the inverse of the sample size being used as the sole predictor variable. The regression coefficient for the inverse of the sample size will be significantly different from the null value (zero) if publication and/or search bias are present in the data.

If significant funnel-plot asymmetry is found, the researcher will need to document the limitation in their report but may also attempt to remedy the asymmetry using the 'trim and fill' method. The trim and fill method essentially involves two stages. First, the researcher identifies and removes effect estimates from the analysis that 'mirror' those that were absent due to publication and/or selection bias. The reduced set of effect estimates (exhibiting symmetry via the Egger test) is analyzed and the results compared to those from the full set of effect estimates. Second, the full set of effect estimates is augmented by the addition of effect estimates thought to closely resemble those missing due to bias. This augmented set of effect estimates (exhibiting symmetry via the Egger test) is also analyzed and the results compared to those from the original full set of effect estimates. Through these comparisons, the robustness of the set of effect estimates can be gauged, with the results from the analyses of both the reduced and augmented sets providing some insight into how the results of the analysis may differ if publication and/or selection bias were not present.

Analyzing Data Heterogeneity

Of all the aspects of meta-analysis, by far the greatest methodological effort has been spent working on the problem of unaccounted heterogeneity in one's data. Multiple techniques have been developed for identifying the presence of data heterogeneity and for quantifying its magnitude.

The most basic tool for assessing between-study heterogeneity in any type of systematic literature review is the pairing of a qualitative assessment of patterns among the relevant studies with a graphical assessment of the magnitude, direction, and level of statistical significance for the effect estimates from the studies. The graphical portion of this assessment, known as a *forest plot*, shows all of the effect estimates and corresponding confidence intervals against a line, which represents the null/no effect value (see Figure 2). A researcher systematically examines the characteristics of the samples on which the relevant studies were based and attempts to qualitatively evaluate whether there is any relationship between study attributes and the results reported. For example, if a researcher notices that most of the effect estimates that are on the left side of the forest plot come from samples of men, while most of the effect estimates that are on the right side of the forest plot come from samples of women, they might conclude that gender heterogeneity is impacting the results of the analysis (and that gender is likely an important moderating variable).

Another basic tool, which is used solely to determine the presence/absence of data heterogeneity among a set of effect estimates, is *Cochrane's Q-test*. To calculate the Q-test statistic, one calculates a weighted sum (where w_i again denotes the inverse variance weight associated with a particular effect

Figure 2 Example forest plot.

estimate) of the squared deviations between each effect estimate (again denoted as ES_i) and the overall mean effect estimate from the meta-analysis (again denoted as $\overline{ES}$) using the following formula:

$$Q = \frac{\sum\left[w_i\left(ES_i - \overline{ES}\right)^2\right]}{\sum w_i}$$

The Q-test statistic follows a χ^2 distribution with $k-1$ degrees of freedom, where k refers to the number of effect estimates being examined. The null hypothesis is that variation between effect estimates is random; a rejection of the null hypothesis indicates that a significant degree of nonrandom heterogeneity exists.

A third tool, called an I^2 *test*, was recently developed by Higgins and Thompson (2002) as a way to assess the magnitude of data heterogeneity when present, rather than simply its presence or absence. The I^2 statistic is calculated solely using information on the value of Cochrane's Q-test statistic and the number of effect estimates included in the analysis (k) using the following formula:

$$I^2 = \frac{Q-k-1}{Q} \cdot 100\%$$

In cases where Q is less than $k-1$, the value of I^2 is set to zero. This statistic indicates the percentage of the variation between effect estimates that is due to heterogeneity alone (as opposed to occurring by chance).

The final commonly used tool for diagnosing the presence of heterogeneity in the data is the *random effect variance component* (v statistic). Hand calculation of this particular statistic is difficult, and is best handled using statistical software. The null hypothesis, again, is that the data are homogeneous. This claim is tested using a basic t-test, where the test statistic is the v statistic divided by its standard error.

Together, these measures of data heterogeneity guide the researcher's decisions on whether to use fixed-effects or random-effects analyses, whether to conduct subgroup analyses, and whether to conduct a meta-regression. A fixed-effects meta-analysis has an assumption that the data are homogeneous (i.e., any variability present is random) while a random-effects meta-analysis assumes that each effect estimate may be drawn from a different population (and thus that both random variation and true variation between populations might exist). Thus, a random-effects model is likely more appropriate when data heterogeneity is present, regardless of whether or not the researcher has any ideas of the source of the heterogeneity.

If the researcher has some idea of the confounding, mediating, and/or moderating factors that might distinguish between study samples and therefore be the source of data heterogeneity, they can pursue strategies to measure the effects of these factors on the overall meta-analysis results. The first method for doing so involves stratifying the full set of effect sizes into subgroups based upon the values of a third variable. For example, researchers commonly conduct separate meta-analyses for men and women. Other basic demographic factors such as age, socioeconomic status, and race/ethnicity are also commonly used to define subgroup meta-analyses. The second method for examining the sources of data heterogeneity is meta-regression, which I will discuss later in this article.

Standardizing Meta-Analysis Reporting

As meta-analysis has progressed as a technique, a series of efforts have been made to elucidate best practices, including the work of the *Cochrane Collaboration* and the creation of the reporting guidelines known as QUOROM (The Quality of Reporting of Meta-analyses) and PRISMA (Preferred Reporting Items of Systematic reviews and Meta-Analyses). While the focus of the present article leans as much as possible toward the social and behavioral scientist, it must be acknowledged that the bulk of this work was undertaken by scholars in the medical disciplines.

The first effort toward standardizing meta-analytic practice emerged in 1993 with the formation of the *Cochrane Collaboration* (www.cochrane.org). The broad goal of the new organization was to promote evidence-based medicine – the idea that an overt effort was needed in order to systematically identify and promote the 'best practices' that current medical research could provide. A major part of this effort involved the increased use of meta-analyses of small-scale clinical trials to more rapidly identify medical treatment advances that should be studied using large-scale trials. One major obstacle was the lack of a centralized place where practitioners and researchers could access meta-analyses and other types of systematic reviews. The primary contributions of the *Cochrane Collaboration* were the creation of a reviews database and the active promotion of systematic review methods in medical research.

A second major obstacle to using meta-analysis to advance evidence-based medicine was the inconsistencies in the quality of meta-analytic practice and reporting. An initial attempt to address this issue was begun in 1996 by a group of 30 clinical epidemiologists, clinicians, journal editors, and medical researchers. This group met with the purpose of systematically developing a set of meta-analysis reporting recommendations, and the resulting recommendations became known as the QUOROM statement, which was issued in its final form in 1999. An updated set of guidelines known as the PRISMA statement (see http://www.prisma-statement.org/index.htm) was issued in 2009.

The PRISMA statement suggests 27 items that every systematic review should contain. These include ensuring the title clearly identifies the paper as a systematic review, meta-analysis, and/or meta-regression and ensuring the abstract contains information on the study design. The statement also suggests that explicit hypotheses and study rationale be provided, and that the methods section clearly documents how the literature search was conducted, how the study inclusion–exclusion determination was made, how the data were collected and coded, how study quality was assessed, and how data heterogeneity was investigated. The statement suggests that the presentation of results should include a flow diagram showing how many studies were considered (and subsequently either retained or eliminated) at each stage of the literature search process. The statement also suggests that meta-analysts report key descriptive information (e.g., study size, sample demographics, individual study results) for the studies included in the analysis (and directly identify these studies through citations). The use of a forest plot (described earlier) is specifically recommended as part of the reporting guidelines. Finally, the PRISMA statement suggests that meta-analysis results should, at a minimum, provide the mean effect estimate, a confidence interval for this estimate, and report the

results of Cochrane's Q-test and/or the I^2 statistic. Recommendations are also made with respect to the discussion section and with regard to the identification of outside funding sources.

Extensions of Meta-Analysis

Though still in its emergent phase, there is a trend toward expanding the number of effect estimates included in an analysis in order to examine data heterogeneity. This trend stands in contrast to the existing norm of eliminating as much heterogeneity as possible before proceeding with one's analysis. In this final section of this article, I will describe the methodological work that is presently underway that allows for including multiple effect estimates from a single study and I will describe meta-regression methods (which I earlier argued were a key tool for quantifying the effects of confounding, mediating, and/or moderating factors).

One major assumption underlying meta-analysis is that the effect estimates included in the study are independent. Ideally, this means that only one effect estimate is taken from each study and that each study included in the meta-analysis is based on a unique sample of people. It is common, however, for studies to present results from subgroup analyses or otherwise stratify their results in ways that make the selection of a single effect estimate difficult. Previously, if no overall effect estimate was directly reported in a study, the meta-analyst was encouraged to use the meta-analysis procedure on the set of effect estimates within this type of study in order to produce the desired overall effect estimate.

Focusing only on single, independent effect estimates from eligible studies substantially reduces the researcher's ability to investigate data heterogeneity. In fact, within-study variations between men and women, age groups, and the like form a powerful basis for examining heterogeneity. An argument can therefore be made that the meta-analyst should seek subgroup effect estimates even if an overall effect estimate is available. Including multiple effect estimates from a single study (or from multiple studies reporting results based on the same data source) introduces a violation of effect estimate independence that must be accounted for. Hedges et al. (2010) discuss this in detail and suggest a method for calculating robust variance estimates for this situation.

Meta-regression becomes the analytic tool of choice when the researcher increases the number of effects estimates included in the analysis (by obtaining multiple effect estimates from individual studies or simply by seeking to expand the number of studies included in the analysis). Meta-regression is also, as previously argued here, the tool of choice when the researcher's focus is the analysis of data heterogeneity rather than solely the calculation of a single meta-analytic estimate of the mean effect.

Meta-regression is an examination of the effect of one or more covariates on the magnitude of the effect estimates reported in the studies included in the analysis. Effectively, meta-regression uses a weighted least-squares model, using the inverse of the variance as the weighting variable (i.e., the same weighting variable used in meta-analysis). The dependent variable is the effect estimate itself, though the effect estimate must be in a form that follows a normal distribution. This means that if one's effect estimates are ratio measures of risk or hazard (i.e., from logistic, Poisson, negative binomial, proportional hazards regression, etc.), one must use the log of the relative risk (i.e., log-odds, log of the rate ratio, log hazard, etc.) as the dependent variable. Either a fixed-effects (fixed partial slopes, single fixed intercept) or a random-effects (fixed partial slopes, random intercept) meta-regression can be specified.

The coefficients produced through a meta-regression indicate the amount by which the magnitude of the effect estimate changes for every one-unit increase in a particular covariate. If the effect estimate takes the form of a log-odds, log-rate, or log-hazard, the researcher can calculate an exponentiated coefficient, which represents a multiplicative indicator of the effect of a one-unit increase in the covariate on the magnitude of the effect estimate. The interpretation of exponentiated coefficients must be done with care however, as they often closely resemble the output from a meta-analysis. For example, suppose you are examining a set of odds ratios from a set of studies focusing on a binary outcome. Suppose further that some of the studies examined samples of men, while others examined samples of women. To prepare the data for meta-regression, one would need to create a binary covariate for the sex of the sample and calculate the log of each odds ratio for use as the dependent variable. Suppose the coefficient for the sex covariate was 0.28. If the covariate were coded such that a value of 0 indicated a study sample consisting of men and a value of 1 indicated a study sample consisting of women, this would indicate that the mean log odds for the outcome of interest was 0.28 higher for women than for men. Exponentiating the coefficient (i.e., $e^{0.28}$) yields 1.32, which indicates that the odds of the outcome of interest for women is 1.32 times the odds of the outcome of interest for men. The 1.32 describes the relative magnitude of the odds ratios for women and men, but does not indicate anything about what the odds of the outcome itself is.

The superiority of meta-regression to subgroup meta-analyses for the analysis of data heterogeneity is relatively obvious. With the subgroup meta-analysis approach, one can only examine one intervening covariate at a time. With meta-regression, one can control for and examine the effects of multiple potential covariates. The difference in the analytic power of the two approaches is akin to the difference between a bivariate regression and a multivariate regression.

Conclusion

In sum, many refinements have been introduced to the quantitative form of systematic review known as a meta-analysis. A tool that was originally proposed to magnify the statistical power of small, relatively homogeneous experimental studies is now routinely used to guide research synthesis across the social and medical sciences. Standards for conducting and reporting the results of meta-analyses have emerged. Of the many advances made, the most attention has been paid to the issue of data heterogeneity. Early work on this issue focused on ways to identify the presence and magnitude of heterogeneity in order to help the researcher eliminate its effects. More recent work has sought to leverage heterogeneity in order to develop

better understandings of the pathways through which social (and other) factors lead to any number of outcomes of interest.

Abstract

Meta-analysis is the combination of estimates across studies for the purposes of drawing general conclusions. Meta-analysis usually summarizes the results of each study by an index of effect size and estimates of effect sizes are combined across studies. Effect sizes are often combined by computing a weighted average to estimate the mean effect size. In that case, assessments of the possible heterogeneity of effects are important. Variation of effects across studies can be studied using linear models (so-called metaregression).

A basic tenet of scientific work is that research findings must be replicable and that studies making important findings are subjected to replication. Often studies are replicated several times, with major or minor variations in research design, research procedures, or measurement methods. Some form of research synthesis or systematic reviewing is essential to determine whether results from different studies are consistent, and to summarize the evidence across studies. Meta-analysis is the use of statistical procedures in that endeavor; it differs from secondary analysis in that the information from each study comes from statistical summaries of the data in the original studies and not directly from the raw data (Glass, 1976). Meta-analysis is a fundamental scientific activity that is practiced in all of the empirical sciences and the fundamental statistical principles underlying meta-analysis are essentially the same in all applications of meta-analysis (Draper et al., 1993).

In meta-analysis, the results of individual studies are represented by a measure of effect size. Study provides an estimate of the effect-size parameter in that study and a measure of statistical uncertainty (variance) of that estimate. The meta-analysis then summarized these effect-size estimates across studies by estimating the distribution of effect-size parameters (often by an estimate of the mean and variance of the distribution of effect size-parameters). The analysis may model the variation in results across studies by estimating the relation between study level characteristics of studies and effect size. This article provides an introduction to the analytic tools most widely used in meta-analysis.

Effect Sizes

A major problem in research synthesis is that studies differ in the details of design and data collection. Effect-size measures are used to represent the outcome of each study so that the results of different studies are comparable, even though there may be differences in the ways the studies collect or analyze data. The appropriate effect size depends on the design of the studies and the nature of the outcome variable. In experimental studies that contrast treatments and employ continuous outcome variables, the standardized mean difference (the difference between the treatment and control group means divided by the within-group standard deviation) is often used (see Borenstein, 2009). In experimental studies with dichotomous outcomes, the effect sizes are typically odds ratios or risk ratios (see Fleiss and Berlin, 2009). When both the independent and dependent variables are continuous, correlation coefficients or standardized regression coefficients are appropriate effect sizes (see Becker, 2009). Each study in a meta-analysis provides both an estimate of effect size and a standard error that indicates the sampling uncertainty of the estimate. In most cases, effect-size estimates are approximately normally distributed; transformations (such as the log of odds ratios and risk ratios or the Fisher z-transform of the correlation coefficient) are often used to improve the normal approximation.

Estimating the Mean and Variance of the Effects across Studies

Estimation of the average effect size across studies involves combining the individual effect-size estimates from different studies, usually by averaging. Because some studies (i.e., those with larger sample sizes) produce estimates with lower uncertainty than others, it is common practice to weight the effect-size estimates when computing the average. A standard result is that weighting proportionally to the inverse of the variance (squared standard error) of each effect-size estimate produces the weighted mean with the smallest variance, so inverse variance weights are usually used. Weighting is used to increase precision of the combined estimate; it has no effect on bias.

Inference Models

There are two sorts of questions that meta-analysis can address. The analyst may inquire about the parameters underlying the particular set of studies observed in the meta-analysis, or there may be more general interest in a putative population of studies that could exist. These questions require different inference models, designated conditional and unconditional (Hedges and Vevea, 1998).

The conditional inference model involves generalizations to the particular parameters in the set of studies that are actually observed in the meta-analysis (or in studies that are, a priori, equivalent to them). For example, conditional inference about the mean effect size in a set of studies addresses the mean of the effect-size parameters in these particular studies; the effect

sizes of any other studies are conceptually irrelevant. The only uncertainty in the conditional inference model arises because the sample effect-size estimate in each study is not identical to the effect-size parameter that it estimates; rather, there is random variation associated with the sampling of persons (or other units) in the studies. Conditional inference may be appropriate, for example, when a particular set of studies has been commissioned to answer a particular question (e.g., a regulatory question), and these studies provide the entire evidentiary base on which a policy question is to be determined.

In contrast, the unconditional inference model involves inferences about the parameters of a universe or hyperpopulation of studies from which the observed studies are a sample. The hypothetical other studies in this universe are conceptually relevant. Because the observed studies are regarded as a sample from the universe, there is additional uncertainty arising from the process of sampling studies. Thus, the effect-size estimate of a study involves a component of uncertainty associated with the sampling of units into that study, and an additional component associated with the sampling of the study itself. The unconditional inference model can also be seen as a Bayesian model where the hyperpopulation of studies is conceived as generating a prior distribution of study effect-size parameters (*see* Bayesian Statistics). The unconditional model may be appropriate when combining evidence about a treatment that is implemented somewhat differently in every study, giving rise to a distribution of treatment effects corresponding to variation in implementation.

Inference models are distinguished from the statistical procedures described below because the type of inference intended is logically prior and should determine the statistical procedures that are used. Fixed-effects statistical procedures are appropriate for conditional inferences and random-effects or Bayesian procedures are appropriate for unconditional inferences.

Fixed-Effects Statistical Procedures

Fixed-effects statistical procedures are designed to make conditional inferences. Let $\theta_1,\ldots,\theta_k$ be the effect-size parameters from k independent studies; let $T_1,\ldots,T_k$ be the corresponding estimates observed in the studies, and let $v_1,\ldots,v_k$ be the variances (squared standard errors) of those estimates. These v_i are called the estimation error variances because they reflect the variance of the estimation errors (the $\varepsilon_i = T_i - \theta_i$).

We typically assume that the T_i is independent and each T_i is approximately normally distributed given θ_i. Note that the normality assumption may not be realistic in all situations. Where it is not, other procedures are needed that are adapted to the particular situation. If the effect-size parameters are equal or nearly so (that is if $\theta_1 = \cdots = \theta_k = \theta$), then the fixed-effects estimate of θ is the weighted mean $\overline{T}_{\bullet}$, given by

$$\overline{T}_{\bullet} = \frac{\sum_{i=1}^{k} w_i T_i}{\sum_{i=1}^{k} w_i} \qquad [1]$$

where the weight $w_i = 1/v_i$. The variance of $\overline{T}_{\bullet}$ is the reciprocal of the sum of the weights

$$\sigma_{\bullet}^2 = \frac{1}{\sum_{i=1}^{k} w_i} \qquad [2]$$

and the standard error $SE(\overline{T}_{\bullet})$ of $\overline{T}_{\bullet}$ is the square root of $\sigma_{\bullet}^2$; that is, $SE(\overline{T}_{\bullet}) = \sigma_{\bullet}$. Because $T_1,\ldots,T_k$ are normally distributed, it follows that the linear combination $\overline{T}_{\bullet}$ is also normally distributed.

If $T_1,\ldots,T_k$ all estimate the same underlying effect size, that is if $\theta_1 = \cdots = \theta_k = \theta$, then $\overline{T}_{\bullet}$ estimates θ, and a $100(1-\alpha)$-percent confidence interval for θ is given by

$$\overline{T}_{\bullet} - C_{\alpha/2}\sigma_{\bullet} \le \theta \le \overline{T} + C_{\alpha/2}\sigma_{\bullet} \qquad [3]$$

where $C_{\alpha/2}$ is the two-tailed critical value of the standard normal distribution (e.g., $C_{\alpha/2} = 1.96$ for $\alpha = 0.05$) and $\sigma_{\bullet}^2$ is the sampling variance of $\overline{T}_{\bullet}$ (eqn [2]). If the confidence interval does not include zero, we reject the hypothesis that $\theta = 0$ at the 100α-percent significance level (*see* Estimation: Point and Interval; Hypothesis Testing in Statistics).

To assess the heterogeneity of effect parameters in fixed-effects models, a test of the hypothesis that $\theta_1 = \cdots = \theta_k$ is often employed. The test uses the statistic

$$Q = \sum_{i=1}^{k} w_i \left(T_i - \overline{T}_{\bullet}\right)^2 = \sum_{i=1}^{k} w_i T_i^2 - \frac{\left(\sum_{i=1}^{k} w_i T_i\right)^2}{\sum_{i=1}^{k} w_i} \qquad [4]$$

which has a chi-square distribution with $k-1$ degrees of freedom when the effect-size parameters are the same in all studies. Large values of Q lead to rejection of the hypothesis that the effect sizes are homogeneous.

Random-Effects Statistical Procedures

Random-effects statistical procedures are designed to make unconditional inferences. That is, they allow inferences about effect-size parameters in a universe of studies from which the observed studies are a sample. Use the same notation for effect-size parameters, their estimates, and the sampling error variances of the estimates. Let $\mu_{\bullet}$ be the mean of the population from which the effect-size parameters $\theta_1,\ldots,\theta_k$ were sampled; let τ^2 be the variance of that mean. The model for the effect-size estimates is

$$T_i = \theta_i + \varepsilon_i = \mu_{\bullet} + \xi_i + \varepsilon_i \qquad [5]$$

where $\xi_i = \theta_i - \mu_{\bullet}$ is a study-specific random effect and $\varepsilon_i = T_i - \theta_i$ is the estimation error as in the fixed-effects model. Thus τ^2 is the variance of θ_i and represents a component of variation due to between-study differences in effect parameters.

The most frequently used procedure estimates $\mu_{\bullet}$ by a weighted mean of the effect-size estimates using slightly different weights from those employed in the fixed-effects procedure. Here, the weights include the additional component of variation, τ^2, which describes between-study variation in effect-size parameters. The unconditional variance v_i^* of T_i is

$$v_i^* = v_i + \tau^2 \qquad [6]$$

where the asterisk denotes that this is the unconditional or random-effects variance. The weights used to compute the weighted mean are $w_i^* = 1/v_i^*$. Note that an estimate of τ^2

will typically be used to estimate the weights in practice (see The section 'Estimating τ^2'). The random-effects

$$\overline{T}^*_{\bullet} = \frac{\sum_{i=1}^{k} w_i^* T_i}{\sum_{i=1}^{k} w_i^*} \quad [7]$$

Note that $\overline{T}^*_{\bullet}$ depends on $\hat{\tau}^2$ because w_i^* does. The variance of $\overline{T}^*_{\bullet}$ is the reciprocal of the sum of the random-effects weights; that is

$$\sigma^{*2}_{\bullet} = \frac{1}{\sum_{i=1}^{k} w_i^*} \quad [8]$$

The standard error $SE(\overline{T}^*_{\bullet})$ of the mean effect estimate $\overline{T}^*_{\bullet}$ is the square root of its sampling variance, $SE(\overline{T}^*_{\bullet}) = \sigma^*_{\bullet}$. If both the effect-size estimates and the effect-size parameters are normally distributed, then $\overline{T}^*_{\bullet}$ is also normally distributed.

An approximate $100(1-\alpha)$-percent confidence interval for the mean effect $\mu_{\bullet}$ is given by

$$\overline{T}^*_{\bullet} - C_{\alpha/2}\sigma^*_{\bullet} \le \mu_{\bullet} \le \overline{T}^*_{\bullet} + C_{\alpha/2}\sigma^*_{\bullet}, \quad [9]$$

where $C_{\alpha/2}$ is the two-tailed critical value of the standard normal distribution and $\sigma^{*2}_{\bullet}$ is the variance of $\overline{T}^*_{\bullet}$ given in eqn [8]. If the confidence interval does not include zero, one rejects the hypothesis that $\mu_{\bullet} = 0$ at the 100α-percent significance level.

Estimating τ^2

Unlike the v_i, which can usually be computed using analytic results (formulas that involve sample size and the effect-size estimate), τ^2 must be computed empirically. Distribution free estimates are usually computed using the methods of moments. The most frequently used estimate of τ^2 in most cases is the distribution free estimate based on the Q-statistic used to test for heterogeneity. The estimate is

$$\hat{\tau}^2 = \frac{Q-(k-1)}{S_1 - S_2/S_1} \quad [10]$$

where S_a is given by

$$S_a = \sum_{i=1}^{k} w_i^a \quad [11]$$

and Q is given in eqn [4]. When eqn [10] produces a negative result, the estimate is set to zero.

The variance of $\hat{\tau}^2$ is given by

$$\frac{2(k-1)S_1 + 4\left(S_1^2 - S_2\right)\tau^2 + 2\left(S_1S_2 - 2S_3 - S_2^2/S_1\right)\tau^4}{S_1^2 - S_2} \quad [12]$$

which reduces to $2(v+\tau^2)^2/(k-1)$ when $v_1 = \cdots = v_k = v$.

If the between-study random effects can be assumed to be normally distributed, then a slightly more efficient estimate of τ^2 can be obtained by maximum likelihood (ML) or restricted ML (REML) estimation. Both of these estimators can be obtained by a simple iterative procedure (see, e.g., Raudenbush, 2009).

The between-studies variance component τ^2 is the natural characterization of between-study heterogeneity in random-effects models. The test for heterogeneity using the Q statistic described in connection with fixed-effects models is also a test of the hypothesis that $\tau^2 = 0$.

Evaluating Heterogeneity

The variance component τ^2 is a direct expression of the variation of the effect-size parameters (the θ_i's). However, to describe the impact of heterogeneity on conclusion of meta-analyses, indices that are functions of τ^2/v (where v is a function (a summary like the average) of the within-study variances) are more useful (see Higgins and Thompson, 2002 for a discussion of this point).

One index is H^2, the ratio of Q to its degrees of freedom (called the Birge ratio in physics (after Birge, 1932)), that is

$$H^2 = Q/(k-1) \quad [13]$$

H^2 has expected value 1 when $\tau^2 = 0$ and there is no heterogeneity. If $v_1 = \cdots = v_k = v$, the expected value of H^2 is

$$E\{H^2\} = (v+\tau^2)/v$$

so H^2 can be interpreted as the ratio of between-study variation $(v+\tau^2)$ to within-study variation (v).

A more useful statistic for many purposes is the ratio of between-study to total variation in the estimates, a kind of intraclass correlation called I^2 (see Higgins and Thompson, 2002). Conceptually I^2 is defined as

$$I^2 = \tau^2/(v+\tau^2)$$

where v is some 'average' value of the v_i. The problem in computing I^2 is choosing a value of v when the within-study variances are not identical. Choosing v to be a weighted average

$$v = \frac{(k-1)\sum_{i=1}^{k} w_i}{\left(\sum_{i=1}^{k} w_i\right)^2 - \sum_{i=1}^{k} w_i^2} = (k-1)/(S_1 - S_2/S_1)$$

where $(S_1 - S_2/S_1)$ is the denominator in eqn [10], yields the conventional definition of I^2, namely

$$I^2 = \frac{Q-(k-1)}{Q} \quad [14]$$

The statistic I^2 is often expressed as a percentage, reflecting the percentage of total variation in the effect-size estimates that is due to between-study heterogeneity.

Bayesian Statistical Procedures

The random-effects procedure above gives an estimate of the average effect size that depends on $\hat{\tau}^2$, which is estimated from the data. When the number of studies is small, the uncertainty of this estimate can be rather large, and a variety of values of τ^2 are almost equally consistent with the data. Bayesian procedures for estimating the average effect size essentially compute the random-effects estimate of the mean conditional on τ^2, and average these conditional means, giving weight to each that is proportional to the posterior probability of τ^2 given the data. Bayesian procedures can also provide improved estimates of individual study effect sizes using information from the entire collection of effect sizes, and have some logical advantages for unconditional inference (for more information see DuMouchel, 1990 or Hedges, 1998).

Robust Standard Errors and Confidence Intervals

Another approach to inference about effect sizes is based on robust standard errors computed from the empirical distribution of the effect-size estimates when the number of studies is large (see Hedges et al., 2010). This approach is similar to that used in econometrics (see, e.g., White, 1980). It is particularly appealing because it makes no assumptions about the (conditional or unconditional) distribution of the effect-size estimates. Moreover, it can be used even when variance estimates for individual effect-size estimates are not available (as occurs when reporting of statistics in studies is very incomplete). While this approach provides no method for computing weights to increase efficiency, standard random-effects procedures can be used to compute (efficient) weights if the estimation error variances are known.

The robust variance estimate of the weighted mean is

$$v_{\bullet}^{R} = \frac{k\sum_{i=1}^{k}\left(w_i^*\right)^2\left(T_i - \overline{T}_{\bullet}^*\right)^2}{(k-1)\left(\sum_{j=1}^{k} w_i^*\right)^2} \qquad [15]$$

which can be used for a robust confidence intervals by substituting $\sqrt{v_{\bullet}^{R}}$ into (9) in place of $\sigma_{\bullet}^*$ and using the critical value of Student's t-distribution with $k-1$ degrees of freedom in place of standard normal critical value. If the robust confidence interval does not include μ_0, one rejects the hypothesis that $\mu_{\bullet} = \mu_0$ at the 100α-percent significance level.

It is important to remember that the validity of inferences based on the robust variance estimate given in eqn [15] depends on having a large sample of studies. However, simulation studies carried out by Hedges et al. (2010) suggest that confidence intervals based on this procedure may be reasonably accurate when there are as few as 10–20 studies if they are (at least approximately) equally weighted.

Statistical Power of Tests in Meta-Analysis

The statistical power of tests in meta-analysis can be quite high when the number of studies is large, but can be quite modest if the number of studies is small and if the variance of the effect-size estimates is large (which typically happens if the sample sizes are small). This is particularly true of tests for heterogeneity of effect sizes across studies. Tests of heterogeneity may often fail to reject the hypothesis of heterogeneity even when effects do actually vary due to low statistical power. Methods for computing the power of statistical tests are beyond the scope of this article but are described in Hedges and Pigott (2001).

Modeling Between-Study Variation in Effect Sizes

The object of the meta-analysis is often to study the variation in effect sizes between studies. This often takes the form of estimating the relation between effect sizes and study-level covariates that may represent methodologically or substantively important characteristics of the studies (such as treatment intensity or dosage, treatment type, study design, subject population). Such modeling must be considered correlational, since there is no random assignment of studies to have different characteristics. Consequently, any such patterns of relations between study-level covariates and effect size should be interpreted with care. It is not unusual for several different covariates to explain essentially the same pattern of variation, which makes interpretations ambiguous.

As in the case of estimating the mean effect across studies, there are two inference models: conditional (which allows inferences about the parameters of the particular studies observed) and unconditional (which allows inferences about the parameters of studies from which the studies observed are considered a sample). In either inference model, the inferences are usually considered conditional on the values of the study-level covariates observed (*see* Linear Hypothesis; Linear Hypothesis: Regression (Basics)).

Fixed-Effects Models

In describing the modeling of between-study variation, it is helpful to use matrix notation. Denote the k-dimensional vectors of population and sample effect sizes by $\boldsymbol{\theta} = (\theta_1,\ldots, \theta_k)'$ and $\mathbf{T} = (T_1,\ldots, T_k)'$, respectively. Suppose that the effect-size parameter θ_i for the ith study depends on a vector of $p \le k$ fixed study-level covariates $\mathbf{x}_i = (x_{i1},\ldots, x_{ip})'$, such as treatment dosage, or length of follow-up. Specifically, assume that

$$\theta_i = x_{i1}\beta_1 + \cdots + x_{ip}\beta_p, \quad i = 1,\ldots,k \qquad [16]$$

where $\beta_1,\ldots, \beta_p$ are unknown regression coefficients.

The $k \times p$ matrix

$$\mathbf{X} = \begin{pmatrix} \mathbf{x}_1' \\ \mathbf{x}_2' \\ \vdots \\ \mathbf{x}_k' \end{pmatrix} = \begin{pmatrix} x_{11} & x_{12} & \cdots & x_{1p} \\ x_{21} & x_{22} & \cdots & x_{2p} \\ \vdots & \vdots & \ddots & \vdots \\ x_{k1} & x_{k2} & \cdots & x_{kp} \end{pmatrix} \qquad [17]$$

is called the design matrix in regression analysis, and is assumed to have no linearly dependent columns; that is, $\mathbf{X}$ has rank p. The first predictor value is often set to 1 (i.e., $x_{i1} = 1$ for all i) so that the first column of $\mathbf{X}$ is a column of ones and β_1 becomes an intercept. The set of equations can be written succinctly in matrix notation as

$$\boldsymbol{\theta} = \mathbf{X}\boldsymbol{\beta} \qquad [18]$$

where $\boldsymbol{\theta} = (\theta_1,\ldots,\theta_p)'$ is the p-dimensional vector of regression coefficients.

The model for $\mathbf{T}$ can be written as

$$\mathbf{T} = \boldsymbol{\theta} + \boldsymbol{\varepsilon} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\varepsilon} \qquad [19]$$

where $\boldsymbol{\varepsilon} = (\varepsilon_1,\ldots,\varepsilon_k)' = \mathbf{T} - \boldsymbol{\theta}$ is a k-dimensional vector of residuals. The linear model $\mathbf{T} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\varepsilon}$ for the effect sizes is analogous to the model that is the basis for ordinary least squares regression analysis. Because $\boldsymbol{\varepsilon} = \mathbf{T} - \boldsymbol{\theta}$, the distribution of $\boldsymbol{\varepsilon}$ is approximately k-variate normal with means zero and diagonal covariance matrix $\mathbf{V}$ given by

$$\mathbf{V} = \mathrm{Diag}(v_1, v_2, \ldots, v_k) \qquad [20]$$

Because the elements of $\mathbf{V}$ are independent but not identically distributed, we use the method of weighted least squares to obtain an estimate of $\boldsymbol{\beta}$.

The generalized least squares estimator is

$$\widehat{\boldsymbol{\beta}} = \left(\mathbf{X}'\mathbf{V}^{-1}\mathbf{X}\right)^{-1}\mathbf{X}'\mathbf{V}^{-1}\mathbf{T} \qquad [21]$$

which has a normal distribution with mean $\boldsymbol{\beta}$ and covariance matrix $\boldsymbol{\Sigma}$ given by

$$\mathrm{Cov}\left(\widehat{\boldsymbol{\beta}}\right) = \boldsymbol{\Sigma} = \left(\mathbf{X}'\mathbf{V}^{-1}\mathbf{X}\right)^{-1} \qquad [22]$$

The distribution of $\widehat{\boldsymbol{\beta}}$ can be used to obtain tests of significance or confidence intervals for components of $\boldsymbol{\beta}$. If σ_{jj} is the jth diagonal element of $\boldsymbol{\Sigma}$, then a $100(1-\alpha)$-percent confidence interval for β_j, $1 \le j \le p$, is given by

$$\widehat{\beta}_j - C_{\alpha/2}\sqrt{\sigma_{jj}} \le \beta_j \le \widehat{\beta}_j + C_{\alpha/2}\sqrt{\sigma_{jj}} \qquad [23]$$

where $C_{\alpha/2}$ is the 100α-percent two-tailed critical value of the standard normal distribution.

The error sum of squares statistic

$$Q_E = \mathbf{T}'[\mathbf{V}^{-1} - \mathbf{X}\mathbf{V}^{-1}(\mathbf{X}\mathbf{V}^{-1}\mathbf{X})^{-1}\mathbf{X}'\mathbf{V}^{-1}]\mathbf{T} \qquad (24)$$

can be used to test the goodness of fit of the regression model. When the model is correctly specified (that is, when $\boldsymbol{\theta} = \mathbf{X}\boldsymbol{\beta}$), Q_E has a chi-square distribution with $k-p$ degrees of freedom, so that large values of Q_E indicate that fit is poor.

Mixed-Effects Models

As in the fixed-effects model, we assume that each T_i is normally distributed about θ_i with (conditional) variance v_i. However, in the case of the mixed model, the predictor variables are not assumed to explain all of the variation in the θ_i. Rather, there is an additional component of variance τ^2 that is not explained by the p study-level covariates $\mathbf{X}_1,\ldots,\mathbf{X}_p$. The linear model is

$$\theta_i = \beta_1 x_{i1} + \ldots + \beta_{ip} + \xi_i \qquad [25]$$

where $x_{i1},\ldots, x_{ip}$ are the values of the predictor variables $X_1,\ldots, X_p$ for the ith study, $\beta_1, \ldots, \beta_p$ are unknown regression coefficients, and ξ_i is a random effect with variance τ^2.

The $k \times p$ design matrix $\mathbf{X}$, and the k-dimensional vectors of population and sample effect sizes $\boldsymbol{\theta} = (\theta_1,\ldots,\theta_k)'$ and $\mathbf{T} = (T_1,\ldots,T_k)'$, are the same as in the fixed-effects model. The set of equations can be written in matrix notation as

$$\boldsymbol{\theta} = \mathbf{X}\boldsymbol{\beta} + \xi \qquad [26]$$

where $\boldsymbol{\beta} = (\beta_1,\ldots, \beta_k)'$ is the p-dimensional vector of regression coefficients, and $\boldsymbol{\xi} = (\xi_1,\ldots, \xi_k)'$ is the k-dimensional vector of study-specific random effects. The model for the observations $\mathbf{T}$ can be written as

$$\mathbf{T} = \boldsymbol{\theta} + \boldsymbol{\varepsilon} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\xi} + \boldsymbol{\varepsilon} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\eta} \qquad (27)$$

where $\boldsymbol{\varepsilon} = (\varepsilon_1,\ldots,\varepsilon_k)' = \mathbf{T} - \boldsymbol{\theta}$ is a k-dimensional vector of residuals of $\mathbf{T}$ about $\boldsymbol{\theta}$, and $\boldsymbol{\eta} = \boldsymbol{\xi} + \boldsymbol{\varepsilon}$ is a k-dimensional vector of residuals of $\mathbf{T}$ about $\mathbf{X}\boldsymbol{\beta}$.

The distribution of $\boldsymbol{\eta} = \boldsymbol{\xi} + \boldsymbol{\varepsilon}$ has mean zero and a diagonal covariance matrix given by $\mathrm{Diag}(v_1 + \tau^2, v_2 + \tau^2,\ldots, v_k + \tau^2)$. Using the estimate $\widehat{\tau}^2$ in place of τ^2, one may compute the $k \times k$ diagonal matrix $\mathbf{V}^*$, an estimate of the unconditional covariance matrix of $\mathbf{T}$, by

$$\mathbf{V}^* = \mathrm{Diag}\left(v_1 + \widehat{\tau}^2, v_2 + \widehat{\tau}^2,\ldots, v_k + \widehat{\tau}^2\right) \qquad [28]$$

The generalized least squares estimator of $\boldsymbol{\beta}$ under the model using the estimated covariance matrix $\mathbf{V}^*$ is

$$\boldsymbol{\beta}^* = (\mathbf{X}'\mathbf{V}^{*-1}\mathbf{X})^{-1}\mathbf{X}'\mathbf{V}^{*-1}\mathbf{T} \qquad [29]$$

which is approximately normally distributed with mean $\boldsymbol{\beta}$ and covariance matrix $\boldsymbol{\Sigma}^*$ given by

$$\Sigma^* = (\mathbf{X}'\mathbf{V}^{*-1}\mathbf{X})^{-1} \qquad [30]$$

The distribution of $\boldsymbol{\beta}^*$ can be used to obtain tests of significance or confidence intervals for components of $\boldsymbol{\beta}$. If β^*_{jj} is the jth diagonal element of $\boldsymbol{\Sigma}^*$, then an approximate $100(1-\alpha)$-percent confidence interval for β_j, $1 \le j \le p$, is given by

$$\beta^*_j - C_{\alpha/2}\sqrt{\sigma^*_{jj}} \le \beta_j \le \beta^*_j + C_{\alpha/2}\sqrt{\sigma^*_{jj}} \qquad (31)$$

where $C_{\alpha/2}$ is the 100α-percent two-tailed critical value of the standard normal distribution.

Relation to Hierarchical Linear Models

The mixed models considered here are related to the hierarchical linear model, a special case of the general mixed linear model, which finds wide application in the social sciences (*see* Hierarchical Models: Random and Fixed Effects; also Goldstein, 1987; Raudenbush and Bryk, 2002). There is widely available software to estimate and test the statistical significance of parameters in these models, so this software is sometimes used in meta-analysis. In these models, the data are regarded as hierarchically structured, and a model is defined for each level of the hierarchy. Statistical models for meta-analysis are usually two level models, where level I is that of the study and the model for level I is

$$T_i = \theta_i + \varepsilon_i, i = 1, \ldots, k \qquad [32]$$

where ε_i is the estimation error of T_i as an estimate of θ_i. Level II of the model describes between-study variation in the study-specific effect-size parameters (the θ_i). The linear model in eqn [26] above implies a level II model like

$$\theta_i = \beta_1 x_{i1} + \ldots + \beta_p x_{ip} + \xi_i \qquad [33]$$

where ξ_i is a study-specific random effect. Most of the attention in estimating these models has focused on the case where both the ε_i and the ξ_i are normally distributed with zero mean and unknown variances, that is $\varepsilon_i \sim \mathrm{N}(0, v_i)$ and $\xi_i \sim \mathrm{N}(0, \tau^2)$, $i = 1, \ldots, k$.

There are two important differences between the hierarchical linear models usually studied and the model used in meta-analysis. The first is that, in meta-analytic models, the variances of the estimation errors $\varepsilon_1,\ldots,\varepsilon_k$ are not identical across studies. The sampling error variances depend on various aspects of study design (particularly sample size) that are rarely constant across studies. The second is that the estimation error variances in meta-analysis are assumed to be known. Therefore, the model used in meta-analysis is a special case of the general hierarchical linear model where the level I variances are unequal, but known. Software for the analysis of hierarchical linear models can be used for mixed model meta-analysis, if it permits the specification of first-level variances that are unequal but known, as do to the programs HLM (Raudenbush et al., 2000) and SAS PROC MIXED (SAS 6.12, 1996).

Methods for Bayesian analyses of hierarchical mixed linear models are also available (see Seltzer et al., 1996 for a general treatment or DuMouchel, 1990 or Hedges, 1998 for applications to meta-analysis).

Estimating τ^2

The usual distribution free estimator of the residual variance component is given by

$$\widehat{\tau}^2 = (Q_E - k + p)/c \qquad [34]$$

where Q_E is the residual sum of squares from the fixed-effects weighted regression (eqn [24]). If the quantity computed in eqn [34] is negative, the estimate is truncated to zero. The normalizing constant c is given by

$$c = \mathrm{tr}(\mathbf{V}^{-1}) - \mathrm{tr}[(\mathbf{X}'\mathbf{V}^{-1}\mathbf{X})^{-1}\mathbf{X}'\mathbf{V}^{-2}\mathbf{X}] \qquad [35]$$

where $\mathbf{V} = \mathrm{Diag}(v_1,\ldots,v_k)$ is a $k \times k$ diagonal matrix of conditional variances and $\mathrm{tr}(\mathbf{A})$ is the trace of the matrix $\mathbf{A}$.

If the random effects can be assumed to be normally distributed, then ML estimation or REML estimation provide more efficient estimates of τ^2 than the method of moments estimator. While neither method provides unbiased estimates, those based on REML tend to be slightly less biased than the MLE.

The vector $\mathbf{e}_{[s+1]} = (e_{1[s+1]},\ldots,e_{k[s+1]})'$ of residuals on the $(s+1)$st step given by

$$e_{[s+1]} = T - \mathbf{X}\widehat{\boldsymbol{\beta}}^*_{[s+1]} \qquad [39]$$

is used to calculate $\widehat{\tau}^2_{[s+1]}$, the generalized least squares estimate of τ^2 given $\widehat{\boldsymbol{\beta}}^*_{[s+1]}$ and the data.

In the case of ML estimation, compute $\widehat{\tau}^2_{[s+1]}$ the value of τ^2 at the next iteration via

$$\widehat{\tau}^2_{[s+1]} = \frac{\sum_{i=1}^k \left(w^*_{i[s]}\right)^2 \left(e^2_{i[s+1]} - v_i\right)}{\sum_{i=1}^k \left(w^*_{i[s]}\right)^2} \qquad [40]$$

setting any negative estimates of τ^2 to zero. Proceed until the estimates of τ^2 converge (that is, change negligibly with each further iteration). The large sample variance of the ML estimate of τ^2 is given by

$$2 \Big/ \sum_{i=1}^k \left(v_i + \tau^2\right)^{-2} \qquad [41]$$

which is approximated by using the value of $\widehat{\tau}^2_{[s]}$ at the last iteration for τ^2.

In the case of REML estimation, the only difference is that instead of computing the estimate of τ^2 at the $(s+1)$st step $\widehat{\tau}^2_{[s+1]}$ via eqn. [40], compute $\widehat{\tau}^2_{[s+1]}$ via

$$\widehat{\tau}^2_{[s+1]} = \frac{\sum_{i=1}^k \left(w^*_{i[s]}\right)^2 \left(e^2_{i[s+1]} - v_i\right) + \mathrm{tr}\left[\left(\sum_{i=1}^k w^*_{i[s+1]}\mathbf{x}_i\mathbf{x}_i'\right)^{-1}\left(\sum_{i=1}^k \left(w^*_{i[s+1]}\right)^2 \mathbf{x}_i\mathbf{x}_i'\right)\right]}{\sum_{i=1}^k \left(w^*_{i[s+1]}\right)^2} \qquad [42]$$

One method for obtaining ML or REML estimates of τ^2 relies on the fact that if either $\boldsymbol{\beta}$ or τ^2 were known, it would be easy to obtain the least squares estimate of the other. By starting with an initial value of τ^2 and estimating first $\boldsymbol{\beta}$ and then reestimating τ^2, a sequence of estimates can be obtained that converge to the ML or REML estimators of $\boldsymbol{\beta}$ and τ^2 (see Goldstein, 1986).

To compute either estimate, start with an initial estimate $\tau^2{}_{[0]}$ of τ^2 (such as that given in eqn [34]). Then if $\widehat{\tau}^2_{[s]}$ is the estimate of τ^2 on the sth step, the $k \times k$ weight matrix on that step becomes

$$\mathbf{W}_{[s]} = \mathrm{Diag}\left[w_{1[s]}{}^*, \ldots, w_{k[s]}{}^*\right], \qquad [36]$$

where

$$w^*_{i[s]} = 1 \Big/ \left(v_i + \widehat{\tau}^2_{[s]}\right) \qquad [37]$$

The estimate $\widehat{\boldsymbol{\beta}}^*_{[s+1]}$ of $\boldsymbol{\beta}$ on the $(s+1)$st step is given by

$$\begin{aligned}\widehat{\boldsymbol{\beta}}^*_{[s+1]} &= \left(\mathbf{X}'\mathbf{W}_{[s]}\mathbf{X}\right)^{-1}\mathbf{X}'\mathbf{W}_{[s]}\mathbf{T} \\ &= \left(\sum_{i=1}^k w^*_{i[s]}\mathbf{x}_i\mathbf{x}_i'\right)^{-1}\left(\sum_{i=1}^k w^*_{i[s]}\mathbf{x}_i T_i\right)\end{aligned} \qquad [38]$$

The difference between eqn. [40] and eqn. [42] is the second term of the numerator, which adds a small constant to the estimate of τ^2 at each iteration. In either case, the iteration proceeds until the estimates of τ^2 converge (that is, change negligibly with each further iteration) and τ^2 is approximated by the value of $\widehat{\tau}^2_{[s]}$ at the last iteration.

Note that the ML estimate of $\boldsymbol{\beta}$ is just the estimate given in eqn [29] using the ML estimate of τ^2 to compute the weights. Confidence intervals from the distribution of $\widehat{\boldsymbol{\beta}}^*$ can be constructed from the ML estimator using eqn [31].

Metaregression analyses are often used to test for the effects of study-level moderator variables. The power of statistical tests for moderator effects need not always be large, even when the number of studies is large. Understanding the power of statistical tests for moderators may be particularly important when these analyses fail to detect moderator effects. Procedures for computing statistical power in metaregression are discussed in Hedges and Pigott (2004).

Robust Variance Estimation

Another approach to inference about effect sizes is based on variance estimates computed from the empirical distribution of the effect-size estimates. This approach is particularly

appealing for three reasons. First, it makes no assumptions about the (conditional or unconditional) distribution of the effect-size estimates, so it is robust to violations of assumptions that estimates or random effects have any specific (e.g., normal) distributions. Second, this theorem does not require that the study-level covariates be fixed as in other metaregression models. Third, robust variance computations can be used even when variance estimates for individual effect-size estimates are not available (as occurs when reporting of statistics in studies is very incomplete).

There are two disadvantages of this method, however. One is that it provides no method for computing weights to increase efficiency. We recommend that standard random-effects procedures be used to compute (efficient) weights, and then robust variance estimates can be used in conjunction with these weights. A second disadvantage is that it requires a large number of studies. However, simulations carried out by Hedges et al. (2010) suggest that the method performs reasonably well for a single covariate even when the number of studies is as small as 10 to 20.

Suppose that $\widehat{\boldsymbol{\beta}}^*$ is a mixed model estimate of $\boldsymbol{\beta}$ computed using weights w_i^*, $i = 1, \ldots, k$. Then the robust variance estimate $\mathbf{V}^R$ is given by

$$\mathbf{V}^R = \left(\frac{k}{k-p}\right)\left(\sum_{i-1}^{k} w_i^* \mathbf{x}_i \mathbf{x}_i'\right)^{-1} \times \left(\sum_{i=1}^{k} (w_i^*)^2 e_i^2 \mathbf{x}_i \mathbf{x}_i'\right)\left(\sum_{i-1}^{k} w_i^* \mathbf{x}_i \mathbf{x}_i'\right)^{-1} \quad [43]$$

where $e_i = T_i - \mathbf{x}_i \widehat{\boldsymbol{\beta}}^*$ is the residual in the ith study and p is the total number of coefficients in the regression model including the intercept if there is one. The diagonal elements of $\mathbf{V}^R$ can then be used as the variances to construct confidence intervals or significance test for the β_j using eqn [31].

Multivariate Meta-Analysis

We have explicitly assumed that effect sizes are independent in previous sections of this article. The assumption of independence will typically be met if indeed the estimators are derived from different experiments, or if the estimates are derived from independent samples of subjects within the same study. However, not all collections of effect-size estimates can easily be reduced to collections of independent estimators. Statistical dependence arises through the random part of the statistical model. Decomposing the effect-size estimate into $T_i = \theta_i + \varepsilon_i$, we see that dependence can arise via correlations among the estimation errors (the ε_i's) or through dependencies among the effect-size parameters (the θ_i's) or both.

Dependencies among the estimation errors can occur, if a study reports data on several different measures of the same conceptual outcome construct or report the same measure at several different points in time. One may wish to compute an effect-size estimate for each measure, but these effect sizes will usually be correlated because the measures are collected from the same individuals. Alternatively, a study may have several treatment arms that are compared to the same control condition. One may wish to estimate an effect size for each treatment, but the comparison with a common control makes such estimates stochastically dependent.

There are three general approaches to situations in which effect sizes are not independent. One is to discard effect-size estimates for all but one outcome or treatment in each study, so that each study produces a single estimate. This approach leads to independent effect sizes but may be excessively wasteful. A second approach is to combine the correlated effect sizes to create a single synthetic effect size in each study. This approach can preserve the information from all the effects, but may be difficult to implement. The third approach is to analyze the correlated effect-size estimates using a multivariate approach that recognizes their correlation structure. This approach also utilizes all of the information in the effect sizes but can likewise be difficult to implement.

Dependencies among effect-size parameters may occur, for example, if the same investigators carry out several studies that are included in the same meta-analysis and those studies share common methods, samples, or measurements that induce effects to be more alike than those from studies carried out by different investigators.

Combining Correlated Effect Sizes Within Studies

It is sometimes convenient to combine effect-size estimates across studies in two steps. First, the correlated estimators within each study are combined to produce a single synthetic effect-size estimate for each study. This eliminates the correlation of estimation errors within a study as a source of dependence. Then the independent estimators are, in turn, pooled across studies.

Suppose that there are still k studies, but now each study yields a vector $\mathbf{T}_i = (T_{i1}, \ldots, T_{iq})'$, a vector of estimates from a single study with $q \times q$ covariance matrix $\boldsymbol{\Sigma}_i$. It is not necessary for each study to have the same number of estimates, so that q may differ for each study and should properly be denoted q_i to denote the dependence of the study index i, but we drop the subscript i on q in this section for simplicity. If the estimates $T_{i1}, \ldots, T_{iq}$ are reasonably consistent with the model of the same effect size for each component, that is, if

$$\theta_{i1} = \theta_{i2} = \cdots = \theta_{iq} = \theta_{i-} \quad [44]$$

then the investigator may wish to compute an estimate of the common effect size θ_{i-}. The most precise estimate of θ_{i-} is given by

$$\overline{T}_{i-} = \sum_{j=1}^{q} \omega_{ij} T_{ij} \Big/ \sum_{j=1}^{q} \omega_{ij} = \boldsymbol{\omega}_i' \mathbf{T}_i \quad [45]$$

where $\boldsymbol{\omega}_i$ is a $q \times 1$ weight vector given by

$$\boldsymbol{\omega}_i = (w_{i1}, \ldots, w_{ip})' = \boldsymbol{\Sigma}_i^{-1} \mathbf{1} \quad [46]$$

$\mathbf{1}$ is a $q \times 1$ column vector of ones. The weights $\boldsymbol{\omega}_i$ are estimated by using estimates of $\boldsymbol{\Sigma}_i$. In large samples, $\overline{T}_{i-}$ is approximately normally distributed with mean θ_{i-} and variance

$$v_{i-} = 1 \Big/ \sum_{j=1}^{q} \omega_{ij} = 1/1'\boldsymbol{\Sigma}_i^{-1}\mathbf{1}$$

As in the case of univariate meta-analysis, the weights leading to the most efficient weighted mean are proportional to the inverse variance (that is, the inverse of the covariance matrix) and the variance of the weighted mean is the reciprocal of the sum of the weights.

If some of the k studies yield a vector of $q > 1$ effect sizes, eqn [45] can be used to obtain a single estimate of effect size $\overline{T}_{i-}$ for each of those studies. Then the large sample approximation can be used to obtain the variance of $\overline{T}_{i-}$. The result is a series of k independent estimators of effect size, one from each study. These independent effect-size estimators can then be combined using the methods given in the previous sections.

Whenever estimates of effect sizes are being combined it may be advisable to determine whether they seem to be estimating the same quantity. To test, for the ith study, whether the component estimators share a common effect size, that is, whether

$$\theta_{i1} = \theta_{i2} = \cdots = \theta_{iq} = \theta_{i-} \qquad [47]$$

compute the statistic

$$Q_i = \mathbf{T}_i'\mathbf{M}_i\mathbf{T}_i \qquad [48]$$

where $\mathbf{M}_i$ is the matrix

$$\mathbf{M}_i = \boldsymbol{\Sigma}_i^{-1} - \left(\boldsymbol{\Sigma}_i^{-1}\mathbf{1}\mathbf{1}'\boldsymbol{\Sigma}_i^{-1}/\mathbf{1}'\boldsymbol{\Sigma}_i^{-1}\mathbf{1}\right) \qquad [49]$$

When eqn [47] holds, the statistic Q_i has a chi-square distribution with $q-1$ degrees of freedom. Thus the test that $\theta_{i1} = \cdots = \theta_{iq}$ consists in comparing the statistic Q_i with the critical values of the chi-square distribution with $q-1$ degrees of freedom. If the value of Q_i is small or statistically nonsignificant, the investigator might choose to pool the estimates from all components of $\mathbf{T}_i$ to obtain the most precise estimate of θ_i-. The Q_i statistic is analogous to the Q statistic for testing heterogeneity of effects in univariate meta-analysis and reduces to it if the effect-size estimates are uncorrelated.

The practical problem in using the methods described above is that the covariance matrix $\boldsymbol{\Sigma}_i$ of the correlated effect sizes is typically not known precisely. Analytic theory exists for the elements of $\boldsymbol{\Sigma}_i$ for various effect sizes, but the covariance matrix of the effect sizes typically depends on the covariance matrix of the outcome variables on which the effect sizes are based (see Gleser and Olkin, 2009). Because the covariance matrix of the outcomes is usually not known precisely (and even an estimate of the covariance matrix is frequently not reported), it is difficult to compute the covariance matrix of the (statistically dependent) effect-size measures.

A very crude approach in this situation is simply to take an unweighted average of the estimates and to approximate the variance of the average by the average of the variances. Such an approach does make use of all of the estimates, but substantially overestimates the variance. A somewhat less crude approach is to compute the variances analytically (the diagonal elements of $\boldsymbol{\Sigma}_i$) and impute the covariances by imputing (guessing) correlations among the effect sizes, so that $\sigma_{ab} = \rho_{ab}\sqrt{v_{ia}v_{ib}}$, where ρ_{iab} is the imputed correlation, via the variance of T_{ia}, and v_{ib}, the variance of T_{ib}.

Multivariate Mixed Models

When a general linear model analysis of effect-size data is desired, there is nonnegligible covariation among effect-size parameters even after controlling for the factors that are of interest in the analysis. That is, there is greater residual covariation than would be expected from estimation error alone. The mixed model incorporates a component of between-study covariation into the uncertainty of effect-size parameters and their estimates, which has the effect of increasing residual variation.

Assume that each $\mathbf{T}_i$ has a q_i-variate normal distribution about the corresponding $\boldsymbol{\theta}_i$ with known $q_i \times q_i$ covariance matrix $\boldsymbol{\Sigma}_i$, that is.

$$\mathbf{T}_i \sim N(\boldsymbol{\theta}_i, \boldsymbol{\Sigma}_i), i = 1, \ldots, k \qquad [50]$$

Note that we do not require all of the studies to have the same number of effect sizes. We denote the $Q = q_1 + \cdots + q_k$ dimensional column vectors of population and sample effect sizes by $\boldsymbol{\theta} = (\boldsymbol{\theta}_1', \ldots \boldsymbol{\theta}_k')'$ and $\mathbf{T} = (\mathbf{T}_1', \ldots \mathbf{T}_k')'$, respectively.

In the present model, assume that each element of the effect size parameter vector $\boldsymbol{\theta}_i$ for the ith experiment depends on a vector of p fixed concomitant variables.

$$\mathbf{X}_i = \begin{pmatrix} x_{i11} & \cdots & x_{i1p} \\ \vdots & \ddots & \vdots \\ x_{iq_i1} & \cdots & x_{iq_ip} \end{pmatrix}$$

Specifically, assume that

$$\theta_{is} = \beta_1 x_{is1} + \cdots + \beta_q x_{isp}, + \xi_{is} \quad i = 1, \ldots, k; \quad s = 1, \ldots, q_i \qquad [51]$$

where $\beta_1, \ldots, \beta_p$ are unknown regression coefficients and ξ_{is} is a random effect. Partition the vector $\xi = (\xi_1, \ldots, \xi_Q)'$ into k subvectors $\xi_1, \ldots, \xi_k$ each with dimension q_i corresponding to the effects for a given study (that is corresponding to $\mathbf{T}_i$ and ε_i). Then the linear model can be written as

$$\mathbf{T} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\xi} + \boldsymbol{\varepsilon} = \begin{pmatrix} \mathbf{T}_1 \\ \vdots \\ \mathbf{T}_k \end{pmatrix} = \begin{pmatrix} \mathbf{X}_1 \\ \vdots \\ \mathbf{X}_k \end{pmatrix}\boldsymbol{\beta} + \begin{pmatrix} \boldsymbol{\xi}_1 \\ \vdots \\ \boldsymbol{\xi}_k \end{pmatrix} + \begin{pmatrix} \boldsymbol{\varepsilon}_1 \\ \vdots \\ \boldsymbol{\varepsilon}_k \end{pmatrix}$$

where ε_i and ξ_i are normally distributed with covariance matrices $\boldsymbol{\Sigma}_i$ and $\boldsymbol{\Xi}$, respectively, and are independent of one another.

Estimation of the Regression Coefficients and the Covariance Components

If the within-study covariance matrices of the effect sizes (the $\boldsymbol{\Sigma}_i$) are known, the regression coefficient vector $\boldsymbol{\beta}$ and the covariance component matrix $\boldsymbol{\Xi}$ can be estimated by weighted least squares. The usual procedure is to first estimate the covariance component matrix $\boldsymbol{\Xi}$ and then reweight to estimate the regression coefficient vector $\boldsymbol{\beta}$ and its covariance matrix $\boldsymbol{\Sigma}$ (see, e.g., Jackson et al., 2011). There are usually advantages (among them software availability) in considering the problem as a special case of the hierarchical linear model considered in conjunction with univariate mixed model analyses. The multivariate mixed model analyses can be carried out as instances of the multivariate hierarchical linear model (see Thum, 1997), estimating parameters by the method of ML. However, a simpler alternative is available.

Since the sampling error covariance matrix is known, it is possible to transform the within-study model so that the sampling errors are independent (Kalaian and Raudenbush, 1996). For each study perform the Cholesky factorization of each sampling error covariance matrix $\boldsymbol{\Sigma}_i$ so that

$$\sum\nolimits_i = \mathbf{F}_i\mathbf{F}_i' \qquad [52]$$

where $\mathbf{F}_i$ is a known matrix (since $\mathbf{\Sigma}_i$ is a known matrix). Then transform the within-study model to be

$$\mathbf{F}_i^{-1}\mathbf{T}_i = \mathbf{F}_i^{-1}\boldsymbol{\theta}_i + \mathbf{F}_i^{-1}\boldsymbol{\varepsilon}_i \quad [53]$$

The transformed effect-size vector $\mathbf{Z}_i$ given by

$$\mathbf{Z}_i \equiv \mathbf{F}_i^{-1}\mathbf{T}_i$$

has a sampling error vector

$$\tilde{\boldsymbol{\varepsilon}}_i = \mathbf{F}_i^{-1}\varepsilon_i \quad [54]$$

which has covariance matrix $\mathbf{I}$, a $q_i \times q_i$ identity matrix. Thus one might write the within-study (level I) model as

$$\mathbf{Z}_i = \mathbf{F}_i^{-1}\boldsymbol{\theta}_i + \tilde{\varepsilon}_i \quad [55]$$

where the transformed effect-size estimates $\mathbf{Z}_i$ are independent, but the effect-size parameter vector $\boldsymbol{\theta}_i$ is the same as in the original model.

Thus the within-study model (eqn [53]) along with the between-study (level II) model

$$\boldsymbol{\theta} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\xi} \quad [56]$$

is a conventional two-level hierarchical linear model with independent sampling errors at the first level, with identically distributed level I errors that have unit variance. Therefore conventional software can be used to estimate $\boldsymbol{\beta}$ and $\boldsymbol{\Xi}$ by the method of full or REML (as in HLM or SAS Proc Mixed) or iteratively reweighted least squares (as in ML3) can be used to estimate this model provided that the level I variances are constrained to unity.

The Robust Variance Estimator

If the covariance matrices of the effect sizes (the $\mathbf{\Sigma}_{i\cdot}$) are not known, the methods discussed above cannot be used. Moreover, when the number of studies is large; it can be tedious to apply those methods. A much simpler method in practice is a procedure that involves robust estimation of the variance of coefficient estimates in metaregression. This procedure does not require knowledge of the $\mathbf{\Sigma}_i$. For now, assume an arbitrary weight matrix $\mathbf{W} = \mathrm{diag}(\mathbf{W}_1,\ldots,\mathbf{W}_k)$, where $\mathbf{W}_j = \mathrm{diag}(w_{j1}, \ldots, w_{jkj})$ is the mixed model weight matrix for the jth study. The weighted least squares estimate of $\boldsymbol{\beta}$ is

$$\mathbf{b} = \left(\sum_{j=1}^{k}\mathbf{X}_j'\mathbf{W}_j\mathbf{X}_j\right)^{-1}\left(\sum_{j=1}^{k}\mathbf{X}_j'\mathbf{W}_j\mathbf{T}_j\right) \quad [57]$$

The exact variance of $\mathbf{b}$ is

$$\left(\sum_{j=1}^{k}\mathbf{X}_j'\mathbf{W}_j\mathbf{X}_j\right)^{-1}\left(\sum_{j=1}^{k}\mathbf{X}_j'\mathbf{W}_j\mathbf{\Sigma}_j\mathbf{W}_j\mathbf{X}_j\right)\left(\sum_{j=1}^{k}\mathbf{X}_j'\mathbf{W}_j\mathbf{X}_j\right)^{-1}$$

Robust standard errors are obtained by substituting the matrix of cross products of within-study residuals in the jth study for $\mathbf{\Sigma}_j$, that is

$$\mathbf{V}^R = \left(\frac{k}{k-q}\right)\left(\sum_{j=1}^{k}\mathbf{X}_j'\mathbf{W}_j\mathbf{X}_j\right)^{-1} \times \left(\sum_{j=1}^{k}\mathbf{X}_j'\mathbf{W}_j\mathbf{e}_j\mathbf{e}_j'\mathbf{W}_j\mathbf{X}_j\right)\left(\sum_{j=1}^{k}\mathbf{X}_j'\mathbf{W}_j\mathbf{X}_j\right)^{-1} \quad [58]$$

where $\mathbf{e}_j = \mathbf{T}_j - \mathbf{X}_j\mathbf{b}$ is the $(q_j \times 1)$ residual vector in the jth study. Although $\mathbf{e}_j\mathbf{e}_j'$ is a rather poor estimate of $\mathbf{\Sigma}_j$, it is good enough that the robust variance estimator converges in probability to the correct value as the number of studies becomes large (see Hedges et al., 2010). In practice, the robust variance estimator is often adequate when the number of studies is 20–30, but diagnostics and methods of improving the performance of the robust variance estimator in small samples are available (Tipton, in press).

Note that robust variance estimates can be computed using any weights (e.g., equal weights or weights proportional to the sample size in each study), but some weighting schemes lead to more efficient estimators of $\boldsymbol{\beta}$. Weights that are the same for each element of $\mathbf{T}_i$ and are proportional to the sample size of the study are generally close to optimal, if there is not large unexplained between-study heterogeneity in effects. A more detailed discussion of weighting schemes is given in Hedges et al. (2010).

The square roots of the diagonal elements of $\mathbf{V}^R$ are the robust standard errors of the elements of $\mathbf{b}$. The robust test of the hypothesis

$$H_0\colon \beta_j = 0$$

uses the test statistic

$$t_j^R = b_j \Big/ \sqrt{v_{jj}^R} \quad [59]$$

where v_{jj}^R is the jth diagonal element of $\mathbf{V}^R$, which is compared with critical values of Student's t-distribution with $k - p$ degrees of freedom. Note that the degrees of freedom is the number of clusters (not effect-size estimates) minus the number of coefficients (including the intercept) in the regression model. Thus with two predictors, $p = 3$ (the intercept and two slopes). A robust $100(1 - \alpha)$-per cent confidence interval for β_j is given by

$$b_j - C_{\alpha/2}\sqrt{v_{jj}^R} \le \beta_j \le b_j + C_{\alpha/2}\sqrt{v_{jj}^R} \quad [60]$$

where $C_{\alpha/2}$ is the $100(1 - \alpha)$-percent point of t-distribution with $m - p$ degrees of freedom.

Conclusions and Suggestions for Further Reading

There are two basic inference models in meta-analysis (conditional and unconditional) and two classes of statistical procedures used in combining effect-size estimates (fixed- and mixed-effects procedures). Bayesian procedures are closely related to mixed models. In either case, statistical methods that weight estimates by the inverse of the conditional or unconditional variance are used for analysis. Typical analyses involve computing an overall mean effect size, assessing heterogeneity, and modeling variation in effect sizes across studies using metaregression.

Metacognitive Development: Educational Implications

Wolfgang Schneider, Department of Psychology, University of Würzburg, Würzburg, Germany

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Metacognition is broadly defined as cognition about one's own cognitions. Metamemory, one subtype of metacognition that refers to knowledge about memory, has attracted particularly strong research interest in developmental psychology. Given that research devoted to aspects of metamemory and its importance for education has created numerous findings in the field, the impact of memory knowledge on educational outcomes will be discussed in more detail. Moreover, research on the role of metacognitive knowledge in the development of reading and mathematics will be summarized. Overall, findings indicate that most of what will be said about metamemory can be easily generalized to metacognitive knowledge related to a variety of problem-solving activities such as reading and mathematics.

Metacognition is broadly defined as cognition about one's own cognitions. John Flavell's (1979) seminal article on developmental aspects of metacognition and metacognitive monitoring stimulated three decades of empirical and conceptual work in developmental as well as educational and mainstream cognitive psychology. The basic proposal outlined by Flavell was that developmental changes in metacognitive knowledge mediate developmental changes in cognitive performance, including memory, language comprehension, reading, and mathematics. Metamemory, one subtype of metacognition that refers to knowledge about memory, has attracted particularly strong research interest in developmental psychology. Given that research devoted to aspects of metamemory and its importance for education has created numerous findings in the field, the impact of memory knowledge on educational outcomes will be discussed in more detail. Moreover, research on the role of metacognitive knowledge in the development of reading and mathematics will be summarized. Overall, findings indicate that most of what will be said about metamemory can be easily generalized to metacognitive knowledge related to a variety of problem-solving activities such as reading and mathematics.

Conceptualizations and Models of Metacognition

Although the concept of 'metacognition' is now frequently used and investigated in various fields of psychology and education, its history is rather short. The first studies on metacognition were developmental in nature and initiated in the early 1970s by Ann Brown, John Flavell, and their colleagues (for reviews, see Brown et al., 1983; Flavell et al., 2002; Schneider and Pressley, 1997). Although various conceptualizations of the term 'metacognition' have been used in the literature on cognitive development, the concept has usually been broadly defined as any knowledge or cognitive activity that takes as its object, or regulates, any aspect of any cognitive enterprise (cf Flavell et al., 2002). According to this conceptualization, metacognition refers to people's knowledge of their own information processing skills, as well as knowledge about the nature of cognitive tasks, and about strategies for coping with such tasks. Moreover, it also includes executive skills related to monitoring and self-regulation of one's own cognitive activities.

In a now classic paper, Flavell (1979) described three major facets of metacognition, namely, metacognitive knowledge, metacognitive experiences, and metacognitive skills, that is, strategies controlling cognition. Declarative metacognitive knowledge refers to the segment of 'world knowledge' that has to do with the human mind and its doings. According to Flavell et al. (2002), metacognitive knowledge about memory includes explicit, conscious, and factual knowledge about the importance of person, task, and strategy variables for processing and recalling information. For instance, knowing that an older child typically recalls more than a younger child is an indicator of person knowledge, and knowing that the time available for solving a mathematical problem is important for subsequent success indicates task-related metacognitive knowledge. Metacognitive experiences refer to a person's awareness and feelings elicited in a problem-solving situation (e.g., feelings of knowing), and metacognitive skills are believed to play a role in many types of cognitive activity such as oral communication of information, reading comprehension, attention, and memory. These facets of metacognition refer to a person's procedural knowledge, which Brown et al. (1983) referred to as 'knowing how,' and which can be further subdivided into monitoring and self-regulatory functions (see below). For an excellent discussion of more subtle distinctions among various aspects of metacognition, see Kuhn (1999, 2000).

The concept of metamemory was introduced by John Flavell and colleagues to refer to knowledge about memory processes and contents. In their taxonomy of metamemory, Flavell and Wellman (1977) distinguished between two main categories, 'sensitivity,' and 'variables.' The 'sensitivity' category referred to mostly implicit, unconscious behavioral knowledge of when memory is necessary, and thus was very close to subsequent conceptualizations of procedural metacognitive knowledge. The 'variables' category referred to explicit, conscious, and factual knowledge about the importance of person, task, and strategy variables for memory performance. This is also known as declarative metacognitive knowledge. Metamemory about person variables includes

knowledge about how, when, and why one remembers or forgets. Metamemory about task variables comprises knowledge about task influences on memory performance, for instance, knowledge that shorter item lists are easier to remember than long lists. Finally, metamemory about strategies refers to knowledge about advantages and possible problems of memory strategies.

This taxonomy of metamemory was not intended to be exhaustive. Since the late 1970s, a number of other theorists have contributed to the development of metamemory theory (for reviews, see Holland Joyner and Kurtz-Costes, 1997; Schneider, 2010, 2015). For instance, Paris and colleagues (e.g., Paris and Oka, 1986) introduced a component called 'conditional metacognitive knowledge' that focused on children's ability to justify or explain their decision concerning memory activities. The declarative metamemory component introduced by Flavell and Wellman focused on 'knowing that,' whereas conditional metamemory referred to 'knowing why.' The procedural metamemory component, that is, children's ability to monitor and regulate their memory behavior ('knowing how') was thoroughly analyzed by Ann Brown and colleagues (e.g., Brown et al., 1983).

Here, the frame of reference was the competent information processor, one possessing an efficient 'executive' that regulated cognitive behaviors. Brown and colleagues could demonstrate that memory monitoring and regulation processes play a large role in complex cognitive tasks such as comprehending and memorizing text materials.

Although more recent conceptualizations of metacognition have expanded the scope of the theoretical construct, they also make use of the basic distinction between declarative and procedural knowledge. For instance, Wellman (1990) has linked the declarative metacognitive component to the broader concept of children's 'theory of mind,' which focuses on classes of knowledge about the inner mental world and cognitive processes that develop during the preschool years. Pressley, Borkowski, and colleagues have systematically considered declarative and procedural components of metacognition in developing a theoretical model that emphasizes the dynamic interrelations among strategies, monitoring abilities, and motivation (e.g., Pressley et al., 1989). According to their 'good information processing model,' metacognitive knowledge is closely related to the learner's strategy use, motivational orientation, general knowledge about the world, and automated use of efficient learning procedures. All these components are assumed to interact. For instance, specific strategy knowledge influences the adequate application of metacognitive strategies, which in turn affects knowledge. As the strategies are carried out, they are monitored and evaluated, which leads to expansion and refinement of specific strategy knowledge.

It should be noted that conceptualizations of metacognition and metamemory in the fields of general cognitive psychology, social psychology, and the psychology of aging differ from this taxonomy, which is mainly used in the fields of developmental psychology and education. For instance, popular conceptualizations of metacognition in the field of cognitive psychology exclusively elaborate on the procedural component, focusing on the interplay between monitoring and self-control (see Nelson, 1996). On the other hand, when issues of declarative metamemory are analyzed in the fields of social psychology and gerontology, the focus is on a person's belief about memory phenomena and not on veridical knowledge.

Assessment of Metacognitive Knowledge

There are a variety of measures that have been used to capture what children know about memory. Measures assessing declarative metacognitive knowledge are taken without concurrent assessment of cognitive performance, whereas measures of procedural metacognitive knowledge are collected simultaneously with the measure of cognitive activity (concurrent measures). Most measures of declarative, factual knowledge have utilized interviews or questionnaires that focus on knowledge about person variables, task demands, and strategies. Earlier instruments predominantly used in the memory domain suffered from methodological problems, whereas more recent interviews and questionnaires showed better psychometric properties such as sufficient reliability and validity (Schneider and Pressley, 1997). Moreover, it was shown that nonverbal techniques helped in assessing young children's declarative knowledge. For instance, one task required young children to distinguish effective from poor strategies while watching a model executing the strategies on video. In another successful procedure ('peer-tutoring task') older children were asked to tutor a younger child about how to do a certain memory task in order to maximize learning. Peer tutoring is likely more motivating to young children than interviews, and they tend to be more explicit when answering a question of an older child as compared with that of an adult (who already seems to know everything).

Overall, these alternative methods alleviated some of the problems usually related to the use of questionnaire measures. However, these measures still created difficulties when applied to older children and adolescents, particularly when knowledge about text processing was assessed. There is the risk that social desirability factors reduce the validity of outcomes for this target group. Accordingly, more sophisticated measures of metacognition have to be used with older children and adolescents. For instance, Schlagmüller and Schneider (2007) came up with a standardized measure of metacognition that was based on a revised test instrument developed for the International Program for Student Assessment (PISA; see Artelt et al., 2001). This instrument taps adolescents' knowledge of strategies that are relevant during reading and for the comprehension as well as recall of text information. For each of six scenarios, students have to evaluate the quality and usefulness of five different strategies available for reaching the intended learning or memory goal. The rank order of strategies obtained for each scenario is then compared with an optimal rank order provided by experts in the field of text processing. The correspondence between the two rankings is expressed in a metacognition score, indicating the degree to which students are aware of the best ways to store and remember text information.

Procedural metacognitive knowledge has been assessed by measures that are characterized by the presence of

a simultaneous cognitive activity. For instance, in the area of memory research, children and adolescents are asked to judge their memory performance either shortly before, during, or after working on a memory task. The most studied type of procedural metacognitive knowledge is self-monitoring, that is, evaluating how well one is progressing. The developmental literature has focused on performance prediction or ease-of-learning (EOL) judgments, judgments of learning (JOL), and feeling-of-knowing (FOK) judgments. See Brown et al. (1983), Flavell et al. (2002), and Schneider and Lockl (2008) for overviews.

EOL judgments occur in advance of the learning process, are largely inferential, and refer to items that have not yet been learned (Nelson and Narens, 1994). The corresponding memory paradigm is performance prediction. In comparison, JOLs occur, during or soon after, the acquisition of memory materials and are predictions about future test performance on recently studied (and probably still recallable) items. Typically, paired-associate learning tasks are used in this context. After completion of a learning trial, participants are shown the stimuli of a given pair and have to indicate how confident they are whether they will remember the correct item response either immediately or 10 min later. A number of developmental studies also explored children's FOK judgments (e.g., Lockl and Schneider, 2002). These judgments occur either during or after a learning procedure and are judgments about whether a currently unrecallable item will be remembered at a subsequent retention test.

Self-monitoring involves knowing where you are with regard to your goal of understanding and memorizing task materials, whereas self-regulation includes planning, directing, and evaluating one's mnemonic activities (cf Flavell et al., 2002). Some developmental studies addressed aspects of children's control and self-regulation processes such as termination of study (recall readiness) and allocation of study time (see the reviews by Schneider, 2010, 2015). Recall readiness assessments are made after learning materials have been studied at least once. Typically, participants are asked to continue studying until their memory of the materials to be learned is perfect. Another example of self-regulation skills concerns the allocation of study time. This research observes how learners deploy their attention and effort when studying lists of items. For instance, developmental studies on the allocation of study time examined whether school children and adults were more likely to spend more time on less well-learned material. After a first free recall trial, participants had to distinguish between recalled and nonrecalled items (monitoring component), and were then asked to select half of the items for additional study (self-regulation component). One problem with the paradigm of the allocation of study time is that it may not only tap metacognitive processes but may also be influenced by motivational variables (see Schneider and Lockl, 2002).

A number of concerns have been raised about measures of procedural metamemory. However, although there is not a perfect index of metamemory, many of the measurement problems that metamemory researchers confront are similar to measurement problems in other areas of psychology.

Development of Metacognition

Precursors of Metacognitive Knowledge

Since the early 1980s, there has been study of preschoolers' metacognition motivated by Perner's (1991) and Wellman's (1990) conceptualizations of children's theory of mind, which emphasizes important classes of knowledge about the inner mental world that children acquire by the ages of 3–4 years. From this age on, children develop a rudimentary understanding of mental verbs such as 'thinking' or 'remembering' and can separate mental processes from external behaviors associated with them. They then gradually learn to recognize that the mental world can be differentiated into processes such as remembering, knowing, and guessing (that is, they acquire knowledge about distinct mental processes). Although 3- to 4-year-olds are not generally capable of differentiating these processes, older preschoolers already make distinctions that are very similar to those of adults.

The relationship between the development of language, theory of mind development, and metamemory development has only recently been systematically explored in longitudinal studies. For instance, Astington and Jenkins (1999) as well as De Villiers and Pyers (2002) found that language competence predicted theory-of-mind development, but not the reverse. Longitudinal relationships among knowledge of mental verbs, theory of mind, and subsequent metamemory were analyzed in a longitudinal study (Lockl and Schneider, 2007). It was shown that both early theory-of-mind competence and metacognitive vocabulary (i.e., knowledge of mental verbs) affected subsequent knowledge of memory. Findings also indicated that metacognitive vocabulary, theory of mind, and general metamemory improved considerably over the preschool years.

Children's Factual Knowledge About Memory and Cognition

Using sensitive methods that minimize demands on the child, it is possible to demonstrate some rudimentary knowledge of memory-related facts in preschoolers. For instance, they understand mental words, distinguish between important versus less important elements in picture stories, and know about the relevance of retrieval strategies when performing on a hide-and-seek task. Knowledge of facts about memory is more impressive in the elementary-grade years, and much more complete by the end of childhood. Nonetheless, knowledge of memory, in particular, knowledge about the interactions of metamemory variables or understanding of the relative importance of text elements continues to develop.

One of the most important findings is that there is increasing strategy knowledge with increasing age. However, there is also increasing evidence that many adolescents (including college students) have little knowledge of some powerful and important memory strategies (for details, see Pressley and McCormick, 1995). Although metacognitive knowledge increases substantially between young childhood and young adulthood, there seems still much to learn about how to read, comprehend, and memorize complex text materials or to solve mathematical

problems (see Pressley and Afflerbach, 1995; Schneider and Artelt, 2010).

Development of Procedural Metacognition

Compared with the clear-cut age trends demonstrated for declarative metacognitive knowledge, the situation regarding procedural metamemory is less clear. Early research focusing on monitoring showed that even young children seem to possess the relevant skills, particularly when the memory tasks are not very difficult (see reviews by Holland Joyner and Kurtz-Costes, 1997; Schneider and Pressley, 1997). Thus, the ability to monitor one's own memory activities is already well developed in young children and seems to improve continuously during the early elementary school years. However, the evidence regarding developmental trends is not consistent, with some studies showing better performance in younger than in older children (for a review, see Schneider, 2010). More recent studies exploring developmental trends in self-regulation (as well as the interaction between monitoring and self-regulation) were helpful in clarifying the situation.

The available evidence on the development of self-regulation skills shows that there are clear increases from middle childhood to adolescence. Spontaneous and effective use of self-regulation skills occurs only in highly constrained situations during the grade-school years and continues to develop well into adolescence. Comparisons of younger and older children in 'study-time apportionment' tasks indicate that it is the interplay between monitoring and self-regulatory activities that develops with age. That is, when the task is to learn item pairs of varying difficulty, both younger and older children show adequate monitoring skills in that they are well able to distinguish difficult from easy item pairs. However, only the older children allocate study time differentially, spending more time on the difficult than on the easier items. In comparison, younger children typically spend about the same amount of time on easy pairs as they spend on hard pairs. The available studies thus indicate an age-related improvement in the efficient allocation of study time. Developmental differences were not so much observed in the metacognitive knowledge itself but in its efficient application to self-regulation strategies.

Although the available developmental research seems to confirm the basic assumption that monitoring influences control processes, recent research with adults has challenged this position, suggesting that self-regulatory processes influence metacognitive monitoring. For instance, Koriat et al. (2006) proposed that study time is actually used by the learner as a cue for encoding fluency under what they called the memorizing effort heuristic, meaning that easily studied items are more likely to be remembered than items that require more effort to study. Accordingly, metacognitive judgments are basically data driven: study time duration is taken retrospectively as a cue for the feeling of mastery. Thus, greater effort (longer study time) is associated with lower JOLs, suggesting that the cause-and-effect relation is actually from control to monitoring. The results of Koriat et al. (2006) not only confirmed this assumption but also showed evidence for the 'monitoring affects control' hypothesis, indicating that the relationships between monitoring and control can be more complex than originally assumed. First developmental studies on this issue confirm the assumption that this is also true for children, indicating that evidence for the 'control affects monitoring' model increases with age (e.g., Koriat et al., 2009).

Metamemory–Memory Relations

From a developmental and educational perspective, the metamemory concept seems well suited to explain children's production deficiencies on a broad variety of memory tasks. Empirical research was stimulated by the belief that young children do not spontaneously use memory strategies because they are not familiar with those tasks and thus do not know anything about the advantages of strategy use. This should change soon after children enter school and are confronted with a large number of memory tasks. Experience with such tasks should improve strategy knowledge (metamemory), which in turn should have an impact on memory behavior (i.e., strategy use). Thus, the major motivation behind studying metamemory and its development has been the assumption that, although links between metamemory and memory may be weak in early childhood, they should become much stronger with increasing age.

Overall, the empirical findings do not indicate such a strong relationship. Narrative and statistical meta-analyses have shown that there are moderate, nontrivial quantitative associations between metamemory and memory. For instance, Schneider and Pressley (1997) reported an overall correlation of about 0.40 based on about 60 publications and more than 7000 children and adolescents. Qualitative reviews of the various metamemory–memory relations make obvious, however, that no single statistic could capture the diversity and richness of the findings. In general, the evidence points to a bidirectional, reciprocal relationship between metamemory and memory behavior. Metacognitive knowledge can influence cognitive behavior, which in turn leads to an enhanced metacognitive knowledge.

Although there are several reasons for the fact that the link between metacognition and cognitive performance is not always as strong as it could be, undoubtedly one of the major mediators is motivation. Empirical research has shown that metamemory–memory performance relationships are particularly impressive when participants are highly motivated to achieve a certain goal. Under these circumstances, all available resources will be activated to cope with task demands, including declarative and procedural metacognitive knowledge (cf Borkowski and Muthukrishna, 1995).

From the early 1980s on, multivariate experimental designs and also comprehensive field studies have been used to examine the complex relationships among metamemory, domain knowledge, memory behavior (strategy use), and memory performance, as well as their relationship with other important variables such as intelligence, memory capacity, and motivation (e.g., DeMarie et al., 2004; Schneider et al., 1998). For instance, Schneider et al. (1998) assessed the relationships among verbal intelligence quotient (IQ), memory capacity, domain knowledge, declarative metamemory, use of

a semantic organizational strategy, and recall in a sort-recall task in third and fourth graders. Findings indicated that metamemory was affected by both verbal IQ and memory capacity. Although there was only a modest direct contribution of metamemory to the prediction of recall, the indirect link via strategic behavior was much stronger. As a consequence, individual differences in declarative metamemory explained a large proportion in the variance of the recall data. Similar findings were also reported by DeMarie et al. (2004), who also illustrated the importance of declarative metamemory for explaining individual differences in strategy use and memory performance in different age groups ranging from kindergarteners to fifth graders.

Overall, the findings of various multivariate analyses confirm that the causal relation between metacognitive knowledge and cognitive performance is complex. Metamemory sometimes has an indirect effect on recall, as when knowledge about categorization strategies leads to semantic grouping during the study period, which in turn produces better recall. Moreover, the influence seems to be bidirectional (see Flavell et al., 2002; Schneider and Pressley, 1997). That is, metacognition can influence cognitive behavior, which in turn leads to enhanced metacognition. Finally, many other relevant variables such as IQ, domain knowledge, memory capacity, and motivation significantly contribute to the explanation of differences in cognitive performance. Obviously, these empirical findings are in accord with the core assumptions of the good information processing model (Pressley et al., 1989), which provides a detailed theoretical account of the complexity of these interactional processes.

Metacognition and Education

Metamemory and Educational Processes

During the 1980s and 1990s, numerous studies explored the efficiency of strategy training approaches in school (for a review, see Schneider and Pressley, 1997). The basic assumption was that, although children in most cases do not efficiently monitor the effectiveness of strategies they are using, they can be trained to do so. For instance, in a training program carried out by Ghatala and colleagues (e.g., Ghatala et al., 1986), elementary school children were presented with paired-associate learning tasks. Before studying these lists, some children received a three-component training. They were taught (1) to assess their performance with different types of strategies, (2) to attribute differences in performance to use of different strategies, and (3) to use information gained from assessment and attribution to guide selection of the best strategy for a task. As a major result, it was shown that even children 7–8 years of age can be taught to monitor the relative efficacy of strategies that they are using and to use utility information gained from monitoring in making future strategy selections.

Several studies on the development of memory and metamemory have emphasized the importance of educational contexts for developmental changes. Obviously, most of memory development is not so much a product of age but of education. One way in which parents and teachers facilitate cognitive development is by nurturing the development of children's metacognition. For instance, a cross-cultural study by Carr and colleagues (Carr et al., 1989) examined differences in the amount of instruction that US and German parents provided to their children at home. Carr and colleagues found that German parents, in contrast to US parents, reported more instruction of strategies, checked homework more often, and also used games that promoted thinking. These differences in home instruction were accompanied by superior strategy use by German children on the memory tasks provided in school. Carr et al. (1989) concluded from this that parental instruction is an important facilitator of children's further metacognitive development.

In a recent longitudinal study on memory development from kindergarten age to the end of elementary school, Kron-Sperl et al. (2008) repeatedly presented the children of their sample with a sort-recall memory task without giving any specific strategy cues. When performance of these children was compared with that of random samples of school children who received this task for the first time, substantial practice effects were found. Children of the longitudinal sample not only outperformed the control children regarding strategy use and memory performance, but also showed better task-specific memory. Obviously, it does not require much effort to improve children's strategy knowledge.

Metacognition and School Performance

Another area of metamemory research involves applications of metacognitive theory to educational settings. It was assumed that children's experiences at school must play an important role in shaping their use of and knowledge about how to learn and remember. However, observations of normal classroom situations did not always prove that teachers foster children's metacognitive development. For instance, Moely and colleagues observed in classrooms to find out how elementary teachers instructed strategy use and memory knowledge as they presented lessons to children in Grades K to 6 (see the overview by Moely et al., 1995). Teachers varied widely in the extent to which they focused on how children might adjust or regulate their cognitive activities in order to master a task. Efforts also varied widely depending on the subject matter under consideration. When Moely and colleagues first looked at a broad range of instructional effort, they found low levels of strategy instruction. However, teachers were found to be more likely to offer suggestions for strategy use when teaching math problem solving. Overall, there is broad agreement that one way in which parents and teachers can facilitate cognitive development is by the development of children's metacognition (see Carr et al., 1989; Coffman et al., 2008). Both classic and recent studies on this issue show that there is still room for improvement in this regard, but that considerable progress can be found.

Metacognition, Reading, and Instruction

Although rich strategy instruction is not common in schools, it can be successfully implemented. Several comprehensive research projects focused on reading instruction and

comprehension monitoring (cf Borkowski and Muthukrishna, 1995; Paris and Oka, 1986). A particularly important instructional procedure in this context is reciprocal teaching (Palincsar and Brown, 1984). Reciprocal teaching takes place in a collaborative learning context and involves guided practice in the flexible use of the following four comprehension monitoring strategies: questioning, summarizing, clarifying, and predicting. The novice's role is facilitated by the provision of scaffolding by the expert (teacher). Skills and strategies are practiced in the context of reciprocal teaching dialogues. The teacher and the students take turns leading discussions regarding the contents of a text they are jointly attempting to understand. Overall, this instructional approach has proven to be extraordinarily successful both with normal and learning-disabled students. Teachers using reciprocal instruction assume more responsibility for strategy implementation early in instruction, gradually transferring control over to the students (see Palincsar, 1986 for an extensive description, and Rosenshine and Meister, 1994 for a realistic appraisal of its benefits).

Furthermore, very ambitious programs have been undertaken by Pressley and colleagues in order to evaluate effective instructional programs in US public school systems (see Pressley and McCormick, 1995; Schneider and Pressley, 1997). Strategy instruction was not conducted in isolation, but was viewed as an integral part of the curriculum, and thus was taught as part of language arts, mathematics, science, and social studies. The goal was to simultaneously enhance children's repertoires of strategies, knowledge, metacognition, and motivation. Pressley and colleagues found that effective teachers regularly incorporated strategy instruction and metacognitive information about flexible strategy use and modification as a part of daily instruction. In accord with the assumption of the good information processing model outlined above (cf Pressley et al., 1989), effective teachers did not emphasize the use of single strategies but taught the flexible use of a range of procedures that corresponded to subject matter, time constraints, and other task demands. On most occasions, strategy instruction occurred in groups, with the teachers modeling appropriate strategy use. By comparison, the work by Moely and colleagues (e.g., Moely et al., 1995) illustrated that the effective teaching process described by Pressley and coworkers does not necessarily constitute the rule, and that effective teachers may represent a minority group in elementary school classrooms. Taken together, the careful documentations of instructional procedures carried out by Pressley, Moely, and their research groups have shown that there is a lot of potential for metacognitively guided instructional processes in children's school learning.

Other recent research explores the utility of the metacognition concept in research with older children and adolescents, assessing the predictive potential of metacognitive knowledge and skillfulness in reading and mathematics (e.g., Artelt et al., 2001; Mevarech and Kramarski, 2003; Schneider and Artelt, 2010; Veenman et al., 2005; see also the contributions in Desoete and Veenman, 2006). Overall, these studies confirm the view that metacognitive knowledge and self-regulated, insightful use of learning strategies not only are influential in elementary school children but also predict math performance and reading comprehension in secondary school settings, even after differences in intellectual abilities have been taken into account. They also give evidence that metacognitive knowledge relevant for school-related domains can still be effectively trained in late childhood and early adolescence.

The numerous recent studies on metacognition and reading as well as mathematics confirm the view that metacognitive knowledge and self-regulated, insightful use of learning strategies predicts academic performance in primary and secondary school settings even after differences in intellectual abilities have been taken into account. They also give evidence that metacognitive knowledge relevant for school-related domains normally develops during the course of primary school but is not at peak in adolescence. Findings from various intervention approaches showed that instructional settings including the training of metacognitive skills can be successful from early school age on, and can still be effective in late childhood and early adolescence.

Despite the fact that strategy instruction in classrooms is difficult and that empirical studies are still rare, there are plenty of good reasons to believe that the situation will improve in the future. There are now metacognitive training programs available that provide long-term strategy instruction and promise long-lasting success (cf Schneider, 2010, 2015). One precondition for increasing the use of such metacognition-related teaching is to increase teachers' understanding of the conceptual foundations of effective learning. As long as teachers do not think in information-processing terms, it will be difficult to establish progress in this field. However, recent changes in teacher education let us believe that teachers will understand information processing much better soon, enabling them to implement strategy training programs in the classroom that pay off for most students.

Taken together, the research programs and applied studies outlined above have enhanced greatly our understanding of how to establish long-term strategy instruction in educational contexts that not only is rich in metamemory and motivational enhancement, but also helps most students to accomplish their academic goals.

Abstract

Following a broad appreciation of metaphor in the classical period and its subsequent life in the history of rhetoric, a contrast is drawn in early modernity revealing a period of resistance to metaphor, using the English writers Hobbes and Locke. This contrasts with the uses to which metaphor was put by Vico and Herder whose work challenged the previously understood relation between the literal and the metaphorical and provided a basis for new descriptions of the social, including anthropology and ethnology. Nietzsche marks a significant development proposing that metaphor offers a creative and critical plurality, making an explicit link between metaphor and the theory of persons in relation. Metaphor identifies a new perspective of human experience making it possible for metonymy to identify its parts, synecdoche to elaborate the relations between the attributes of parts to the whole, and irony to inspect the earlier practices for their adequacy, by a test of opposition. The redescription of natural science as having a dependency on metaphor, and the later work of Wittgenstein are each seen as helping to overcome the earlier resistance, opening a possibility for a subsequent burgeoning of academic study of the subject in the closing decades of the twentieth century. Links are described between perspectives on metaphor with anthropology, ethnology, ethnography, ethnomethodology, psychoanalysis, economics, psychology, and sociology. Any further links between metaphor and the achievement of intimacy and community and the ways in which these might be modified by particular social and economic structures yet remain to be developed, although a comprehensive, utopian, and pragmatist redescription of modern culture and politics drawing upon the changing status of metaphor has been offered by Richard Rorty.

Metaphor has resisted any wide agreement as concept, yet the last few decades have witnessed a burgeoning of work and interest in metaphor and its related tropes. The many attempts to theorize metaphor have included, *inter alia*, characterizations of metaphor as 'comparison,' as 'without meaning,' as 'anomaly,' 'speech act,' 'loose talk,' 'interaction,' and 'intentional category mistakes.' These attempts have had the form of trying to assimilate metaphor under a previously existing understanding of language – a move that is itself metaphorical. This resistance to conceptualizing suggests that it might be more helpful to consider metaphor in terms of its uses.

Aristotle

For most of its life metaphor has had its home in rhetoric, and it has been to Aristotle that writers have usually turned for the earliest considerations. He understood it as 'giving a thing a name that belongs to something else,' and thought that 'the greatest thing by far is to have a command of metaphor.' Not all writers have heeded the contexts within which Aristotle wrote. His teacher, Plato, had sufficient doubts about the value of metaphor that he barred poets from his Republic. Aristotle, by contrast, found uses for metaphor, not only in politics where rhetoric enabled a man to be heard effectively in public, but also in law, where juries were suspicious of evidence that could be faked, and witnesses who could be bribed. They were, rather, influenced by arguments turning around a balance of probabilities, providing an important context for rhetoric. Aristotle cannot easily be read as limiting metaphor to the realm of ornament, or efficiency of utterance: he sees clear cognitive uses:

> … strange words simply puzzle us; ordinary words convey only we what we know already; it is from metaphor that we can best get hold of new ideas.
>
> 1984, *Rhetoric* III: 1410b

We may suppose that Aristotle's description of metaphor as giving something a name which belongs to something else, detailed as: "the transference being either from genus to species, or from species to genus, or from species to species, or on grounds of analogy" (1984, *Poetics*: 1457b), also owed something to his practice as taxonomist of the natural world. Although Aristotle's comment on Plato's forms that "(to say) they are patterns and the other things share in them is to use empty words and poetical metaphors" (1984, *Metaphysics*: 991a21), may be taken as evidence of his ambivalence to metaphor, but should rather be understood as evidence of a variety of rhetorical uses. His reference to analogy and his remark that 'to make good metaphors implies an eye for resemblances' has led his theory to be dubbed 'the comparative theory.' Aristotle may be understood, in short, as praising metaphor in poetry and drama, in law, in politics, and in what we might now refer to as natural science.

The subsequent history of metaphor until the end of the Renaissance may best be understood as part of the history of rhetoric.

Early Modernity and Early Resistance to Metaphor

Part of the development of rhetoric in seventeenth century Europe was a 'simplification' of the tropes to just four: metaphor; metonymy in which the name of an attribute or other adjunct is substituted for the intended object as with 'scepter' for 'authority'; synecdoche in which a part signifies the whole; and irony where a term is used which is opposite to the one intended to be read.

The first major philosophy written in English, credited to Thomas Hobbes (1588–1679) and his *Leviathan* (1651), published a year after Descartes' death, is severe on metaphor and claims that, of the seven causes of absurdity "The sixth (is), to the use of metaphors, tropes, and other rhetorical figures, instead of words proper." Yet the opening paragraph of the

English version of the text elaborates what Black (1962) would later call the 'associated commonplaces' of the title image, Leviathan, Hobbes's metaphor for the State. Hobbes was writing in complicated, changing, and dangerous times, with differing purposes, addressing different audiences and with changing beliefs, about which Quentin Skinner has written elucidating the use of rhetoric in a context of humanism, of the growth of science, and the growing tensions with the church (1996). John Locke (1632–1704), following Hobbes, thought that "all the artificial and figurative application of words … (are) in all discourses that pretend to inform or instruct, wholly to be avoided; and where truth and knowledge are concerned, cannot but be thought a great fault." Here began a tradition later called the 'purity thesis,' still sustained in the British Isles at the beginning of the twenty-first century.

Meanwhile, in continental Europe, other voices were heard in praise of metaphor. Giambatista Vico (1668–1744) used metaphor as a tool within philology to produce a theory of 'poetic logic.' This included the notion that names were given to features of the natural world that were already well known, drawing for example upon the body – rivers and bottles were given 'mouths,' etc.

> Whence we derive the following (principle of) criticism for the times in which the metaphors were born in (various) languages. All metaphors which, by means of likenesses taken from bodies, come to signify the labors of abstract minds, must belong to times in which philosophies had begun to become more refined. This is shown by the following: that in all languages the words necessary to cultivated arts and recondite sciences have rural origins.
>
> Vico, 1744: paragraph 404

Vico's view led him to reverse the standard relationship of the poetic to the literal.

> From all this it follows that all the tropes (and they are all reducible to the four types discussed) which have hitherto been considered ingenious inventions of writers, were necessary modes of expression of all the first poetic nations, and had originally their full native propriety. But these expressions of the first nations later became figurative when, with the further development of the human mind, words were invented which signified abstract forms or genera comprising their species or relating parts with their wholes. And here begins the overthrow of two common errors of the grammarians: that prose speech is proper speech, and poetic speech improper; and that prose speech came first and afterward speech in verse.
>
> Vico, 1744: paragraph 409

Vico's theory links the actions of metaphor, metonymy, and synecdoche. Metaphor identifies a new domain of human experience making it possible for metonymy to identify its parts, synecdoche to elaborate the relations between the attributes of parts to the whole, and irony to inspect the earlier practices for their adequacy, by a test of opposition. When irony is correctly detected the new object may be regarded as appropriately established in the consciousness of the person or group. Vico's views were not fully effective until the nineteenth century but views in some respects similar to his were held by Herder (1744–1803), born in the year Vico died. Herder's application was not the diachronic one of Vico, but rather the synchronic, through which he came to celebrate difference in cultures and provided an intellectual basis for the beginnings of anthropology and ethnology.

Some dissident voices were also heard in England. Coleridge (1772–1834), when asked why he attended Davy's chemistry lectures, replied that he wanted to renew his stock of metaphors. Shelley (1792–1822) provided a connection between metaphor, language, and culture:

> Language is vitally metaphorical; that is, it marks the before unapprehended relations of things and perpetuates their apprehension, until words, which represent them, become, through time, signs for portions or classes of thought instead of pictures of integral thoughts: and then, if no new poets should arise to create afresh the associations which have thus been disorganized, language will be dead to all the nobler purposes of human intercourse.

Nietzsche and Freud

Nietzsche (1844–1900) marks a significant development. Moving beyond both Herder and Vico and their celebration of cultural plurality, extending Shelly's view, and in a Darwinian context, he proposed that metaphor serves a creative and critical plurality. With earlier writers we may be tempted to observe that with a change of view of metaphor there seems to be a linked change of the theory of the human being. With Nietzsche, however, the linkage is explicit:

> The drive toward the formation of metaphors is the fundamental human drive, which one cannot for an instant dispense with in thought, for one would thereby dispense with man himself. This drive is not truly vanquished and scarcely subdued by the fact that a regular and rigid new world is constructed as its prison from its own ephemeral products, the concepts.
>
> Nietzsche, 1979: p. 88

Turning towards the domain of philosophy, he remarks in an early writing:

> What then is truth? A movable host of metaphors, metonymies, and anthropomorphisms: in short, a sum of human relations which have been poetically and rhetorically intensified, transferred, and embellished, and which, after long usage, seem to a people to be fixed, canonical, and binding. Truths are illusions that we have forgotten are illusions; they are metaphors that have become worn out and have been drained of sensuous force, coins that have lost embossing and are now considered as metal and no longer as coins.
>
> Nietzsche, 1979: p. 84

The metaphor for truth, of coin which loses its face, has attracted many writers, few of who have commented on the phrase 'a sum of human relations' as applied to the tropes, a perception yet remaining to be developed.

Freud (1856–1939), some 12 years younger than Nietzsche, with mutual intimate acquaintances, made the claim that Nietzsche's "guesses and intuitions often agree in the most astonishing way with the laborious findings of psychoanalysis."

Whatever that relationship might yet turn out to have been, Freud's work had the effect of applying Nietzsche's perceptions to the 'unconscious,' a new metaphor of depth, drawing upon the classical myths for his lexicon – which, in turn, made available rich seams of linked metaphors. I.A. Richards (1893–1979) who provided terms for the study of metaphor: 'tenor,' 'vehicle,' and 'tension.' These terms, though by no means unambiguous, and failing to encompass the full range of metaphors, nevertheless helped to revive talk of metaphor. Richards linked psychoanalysis to metaphor.

> The psychoanalysts have shown us with their discussions of 'transference'—another name for metaphor—how constantly modes of regarding, of loving, of acting, that have developed with one set of things or people, are shifted to another. They have shown us chiefly the pathology of these transferences, cases where the vehicle—the borrowed attitude, the parental fixation, say—tyrannizes over the new situation, the tenor, and behavior is inappropriate. The victim is unable to see the new person except in terms of the old passion and its accidents. The victim reads the situation only in terms of the figure, the archetypal image, the vehicle. But in healthy growth, tenor and vehicle—the new human relationship and the family constellation—cooperate freely; and the resultant behavior derives in due measure from both. Thus in happy living the same patterns are exemplified and the same risks of error are avoided as in tactful and discerning reading. The general form of the interpretative process is the same, with a small-scale instance—the right understanding of a figure of speech—or with a large-scale instance—the conduct of a friendship.
>
> Richards, 1936: p. 135ff.

More recently, Freud's writing has begun to be redescribed in ways that reveal its tropical basis (e.g., Lacan *The Four Fundamental Concepts of Psychoanalysis*) (*see* Psychoanalysis, History of).

The Tide Turns, Natural Science Exposed as Metaphor-Dependent

Quine (1908–2000) writing as an empiricist nevertheless thought it: "a mistake, then, to think of language usage as literalistic in its main body and metaphorical in its trimming. Metaphor, or something like it, governs both the growth of language and our acquisition of it" (1979: p. 160). Mary Hesse has extensively described the work of metaphor in science as compatible with this view. Max Black (1962) offered an 'interactive' theory of metaphor as a development of the 'comparison' view, and further linked metaphor and model, thereby linking the worlds (languages?) of literature and science. In the same year, Thomas Kuhn (1962), offered a sociological description of natural science, one recognized more by sociologists and historians than by philosophers, which had as one of its central notions that of a 'paradigm' which, in some uses, may be taken as a synonym for metaphor. This provided a stimulus for developing a social critique of natural science (see Latour and Woolgar, *Laboratory Life: The Construction of Scientific Facts*). In 1970, Rom Harre distinguished models in science into two kinds, homeomorphs which are modeled upon its subject, as is a doll, and paramorphs where the model is only distantly related, Harré's examples included Harvey's use of hydraulics to model, and discover, the circulation of blood. Paramorphs, close cousins to metaphor, are creative: homeomorphs have heuristic uses only. It is perhaps ironic that the stimulus for much work on metaphor may have come from this identification of the place of metaphor in science.

The Tide Turns, Within the Philosophy of Language

Ferdinand de Saussure (1857–1913) within his structural view of language, made a distinction between paradigmatic and syntagmatic axes that can be seen to correspond to a distinction made by Roman Jakobson (1896–1982) between two types of aphasia. In one, the victims have difficulty with the selection of a term and are dependent upon the context, which is on the contiguity of the discourse to continue to be part of it. By contrast, other aphasics, were seen to substitute equivalent terms e.g., table for lamp, smoke for pipe. Jakobson saw these as examples of metonymy and metaphor on the grounds that these were the most condensed expression of the contiguity or similarity distinctions. This changed perception of the relation between metaphor and metonymy led to developments in structuralism for example, by Levi-Strauss (1908–2009) in anthropology, and by Jacques Lacan (1901–81) in psychoanalysis. Accepting Jakobson's suggestions, David Lodge offered a typology of modern writing based upon an opposition between metaphor and metonymy (1977).

Heidegger's writing is rich with metaphor yet he denied it. He construed the sensory/nonsensory distinction as belonging to metaphysics and drew the conclusion that "the metaphorical exists only within the boundaries of the metaphysical." By expressing a preference for the 'poetical' over the 'mathematical,' Heidegger has been influential in offering a reading of Nietzsche recovering a role for philosophy by means of what we might identify as metaphor of the kind which, as a sentence, is obviously false: "Philosophy is essentially untimely because it is one of those few things that can never find an echo in the present."

Derrida (1930–2004) radicalized Saussure's structural description of language, both in his conceptualizing and also in the style of his writing – in so doing, he matched the congruence in Nietzsche who linked his valuation of metaphor to his style of writing. Derrida's view of language relies upon a play of differences, and understands metaphor as operating within that play of differences – he was unable to use the otherwise conventional distinction between the metaphorical and the literal. His identification of phallogocentrism undermined the metaphor of depth for more perspicuous knowledge, paving the way for a metaphor of breadth. Hans-Georg Gadamer (1900–2002) understood as a major contributor to hermeneutics also wrote of metaphor.

> It is the genius of linguistic consciousness to be able to give expression to these similarities. This is its fundamental metaphorical nature, and it is important to see that it is the prejudice of a theory of logic that is alien to language if the metaphorical use of a word is regarded as not its real sense.
>
> Gadamer, 1960: p. 429

This view strengthens the possibility of substituting a metaphor of breadth for that of depth to describe knowing and understanding, begun by Derrida. Paul Ricoeur (1913–2005) in

a conservative review of the principal writers, sees metaphor as the continuing source for the redescription of the world, but only in a perspective within which philosophy would be concerned to manage the legitimacy of its uses, limiting its influence and restricting any epistemological damage.

While it may be interesting to speculate what part the earlier publication of Ludwig Wittgenstein's (1889–1951) *Tractatus* (1922) might have played in making the *Philosophical Investigations* (1953) as influential as it has proved, the former, though built upon metaphor, has no place for it within its closed system, whereas the latter uses metaphor throughout, but without attempting an explicit theory of it. The style of the *Philosophical Investigations* is as if we hear just one side of a conversation – simply a limitation imposed if the writing is not to be that of drama or a novel? Perhaps the *Investigations* will come to be judged as the writing which, more than any other, licensed the growth of academic interest in metaphor (*see* Hermeneutics; Critical Theory; Linguistic Turn).

The Tide Turns, The Broader Academic Response

Kenneth Burke (1897–1993), following Vico, selected 'metonymy, irony, metaphor and synecdoche' and labeled them the 'Four Master Tropes' and set them to new (as he thought) uses:

> I refer to metaphor, metonymy, synecdoche, and irony. And my primary concern with them here will be not with their purely figurative usage, but with their role in the discovery and description of 'the truth.' It is an evanescent moment that we shall deal with—for not only does the dividing line between the figurative and literal uses shift, but also the four tropes shade into one another. Give a man but one of them, tell him to exploit its possibilities, and if he is thorough in doing so, he will come upon the other three.
>
> 1969: p. 503

Four influential interdisciplinary conferences were held in the academic year beginning September 1977, following the publication of a bibliography, *Metaphor* (Shibbles, 1971). Later, some 3500 publications were identified in the period 1985–90 (van Noppen and Hols, 1990).

In one, came a significant moment with a sharp difference between Max Black and Donald Davidson. Following Richards and Black, it had been normal to speak of 'literal meaning' and 'metaphorical meaning.' Davidson relied upon a distinction between what words mean and what they do, and took metaphor to belong exclusively to the domain of use. The terms used in metaphor should be held to mean exactly what they mean in their literal use.

Andrew Ortony collected an influential number of papers representing a variety of perspectives on metaphor (1979). The rate of change merited a second edition as early as 1993 (1993). Within philosophy, Cooper provided a comprehensive and well received discussion (1986). Seen by many as a significant event, the publication in 1980 by Lakoff and Johnson (1980) of *Metaphors We Live By*, copiously illustrated the endemic nature of metaphor in everyday understanding and extended metaphor's claim to cognitive uses. More recently, this has been developed and broadened by Raymond Gibbs (1994).

By the end of the twentieth century there was scarcely a field of academic enquiry within the behavioral sciences which had not begun to explore its areas of interest with the benefit of an analysis using metaphor and its related tropes as tools e.g., Brown (1977) in sociology, Leary (1990) in psychology, McCloskey (1986) in economics, and much is owed to Hayden White who developed Vico's insights and applied them to the writing of history providing a most virtuous circle (1973, 1985).

Metaphor and 'The Social'

We have, almost in passing, encountered pointers towards a closer association between the metaphorical and the social. Darwin's *Origin of Species* provided the opportunity to replace a view of language as correspondence with reality, with that of a series of tools to support survival. Metaphor in this view is a tool-making tool. Nietzsche referred to the tropes as 'a sum of human relations.' Cohen (1979) drew attention to similarities between metaphors and jokes, and to the experience which he calls the achievement of intimacy:

> There is a unique way in which the maker and the appreciator of a metaphor are drawn closer to one another. Three aspects are involved: the speaker issues a kind of concealed invitation; the hearer expends a special effort to accept the invitation; and this transaction constitutes the acknowledgment of a community.

This description may easily be extended into a research program. Davidson has recently maintained that thought itself absolutely depends on a three way relationship between at least two people and a series of events that are shared in the world.

Critical both of Saussure's 'objectivist' linguistics and of 'subjectivist' perspectives, Bakhtin (1895–1975) developed a view of language as sustained and developed in particular social relationships, in turn embedded in wider political and economic conditions and, paradigmatically, with consciousness being thought of as inhering in the person-within-the-group. This view allows for full social interaction, including the nonverbal, to be understood as modifying the associations which attached to the terms deployed in conversation. Wittgenstein's style in the *Philosophical Investigations* is reminiscent of Bakhtin's view.

Although computer technology has made possible the assembly of large corpora of searchable language texts drawn from a variety of publications, it seems not yet to be practicable to incorporate significant contextual detail into these databases, other than of an immediate textual kind, providing a limitation on the development of a social understanding of metaphor, by this route. For the time being, it would seem that some kind of ethnographic research will be most suited to explore the human-relational sources of metaphor use, with Bakhtin's perspective suggesting the possibility of developments in ethnomethodology. Some suggestions, focusing on 'conversational realities,' have been made by John Shotter (1993) and a comprehensive, utopian, and pragmatist redescription of modern culture and politics drawing upon the changing status of metaphor, has been

offered by Richard Rorty (1989). Metaphor is the meeting place of the human with the natural.

Method of Moments and Generalized Method of Moments

Abstract

This article describes empirical methods for estimating dynamic economic systems using time series data. By design, the methods target specific feature of the dynamic system and do not require a complete specification of the time series evolution. The resulting generalized-method-of-moments estimation and inference methods use estimating equations implied by some components of a dynamic economic system. This article describes the statistical methods and some applications of these methods.

Introduction

In many empirical investigations of dynamic economic systems, statistical analysis of a fully specified stochastic process model of the time series evolution is too ambitious. Instead, it is fruitful to focus on specific features of the time series without being compelled to provide a complete description. This leads to the investigation of partially specified dynamic models. For instance, the linkages between consumption and asset returns can be investigated without a full description of production and capital accumulation. The behavior of monetary policy can be explored without a complete specification of the macroeconomic economy. Models of inventory behavior can be estimated and tested without requiring a complete characterization of input and output prices. All of these economic models imply moment conditions of the form:

$$Ef(x_t, \beta_o) = 0 \qquad [1]$$

where f is known a priori, x_t is an observed time series vector, and β_o is an unknown parameter vector. These moment relations may fall short of providing a complete depiction of the dynamic economic system. Generalized method of moments (*GMM*) estimation, presented in Hansen (1982), aims to estimate the unknown parameter vector β_o and to test these moment relations in a computationally tractable way. This article first compares the form of a *GMM* estimator to closely related estimators from the statistics literature. It then reviews applications of these estimators to partially specified models of economic time series. Finally, it considers *GMM*-related moment-matching problems in fully specified models of economic dynamics.

Minimum Chi-Square Estimation

To help place *GMM* estimation in a statistical context, I explore a closely related minimum chi-square estimation method. Statisticians developed minimum chi-square estimators to handle restricted models of multinomial data and a variety of generalizations. Neyman (1949) and Burankin and Gurland (1951), among others, aimed to produce statistically efficient and computationally tractable alternatives to maximum likelihood estimators. In the restricted multinomial model, estimators are constructed by forming empirical frequencies and minimizing Pearson's chi-square criterion or some modification of it.

The method has direct extensions to any moment-matching problem. Suppose that $\{x_t\}$ is a vector process, which temporarily is treated as being *iid*. Use a function ψ with n coordinates to define target moments associated with the vector x_t. A model takes the form

$$E[\psi(x_t)] = \phi(\beta_o)$$

where β_o is an unknown parameter. The moment-matching problem is to estimate β_o by making the empirical average of $\{\psi(x_t)\}$ close to its population counterpart $\phi(\beta_o)$:

$$\min_{\beta} \frac{1}{T}\sum_{t=1}^{T}[\psi(x_t) - \phi(\beta)]' V \sum_{t=1}^{T}[\psi(x_t) - \phi(\beta)] \qquad [2]$$

where V is the distance or weighting matrix. The distance matrix sometimes depends on the data and/or the candidate parameter vector β. The use of V to denote a weighting matrix that may actually depend on parameters or data is an abuse of notation. This simple notation is used because it is the probability limit of the weighting matrix evaluated at the parameter estimator that dictates the first-order asymptotic properties.

The limiting distribution of the criterion in eqn [2] is chi-square distributed with n degrees of freedom if the parameter vector β_o is known, and if V is computed by forming the inverse of either the population or sample covariance matrix of $\psi(x)$. When β is unknown, estimates may be extracted by minimizing this chi-square criterion, and hence the name. To preserve the chi-square property of the minimum (with an appropriate reduction in the degrees of freedom), we again form the inverse sample covariance matrix of $\psi(x)$, or form the inverse population covariance matrix for each value of β. The minimized chi-square property of the criterion may be exploited to build tests of overidentification and to construct confidence sets for parameter values. Results like these require extra regularity conditions, and this rigor is supplied in some of the cited papers.

While the aim of this research was to form computationally tractable alternatives to maximum likelihood estimation, critical to statistical efficiency is the construction of a function ψ of

 http://dx.doi.org/10.1016/B978-0-08-097086-8.42029-5

the data that is a sufficient statistic for the parameter vector (see Burankin and Gurland, 1951). Berkson (1944) and Taylor (1953) generalize the minimum chi-square approach by taking a smooth one-to-one function h and building a quadratic form of $h\left[\frac{1}{T}\sum_t \phi(x_t)\right] - h[\psi(\beta)]$. Many distributions fail to have a finite number of sufficient statistics; but the minimum chi-square method continues to produce consistent, asymptotically normal estimators provided that identification can be established.

GMM estimators can have a structure very similar to the minimum chi-square estimators. Notice that the core ingredient to the moment-matching problem can be depicted as in eqn [1] with a separable function f

$$f(x,\beta) = \psi(x) - \phi(\beta)$$

used in the chi-square criterion function. Target moments are one of many ways for economists to construct inputs into chi-square criteria, and it is important to relax this separability. Moreover, in *GMM* estimation, the emphasis on statistical efficiency is weakened in order to accommodate partially specified models. Finally, an explicit time series structure is added, when appropriate.

GMM Estimation

Our treatment of *GMM* estimation follows Hansen (1982), but it builds from Sargan's (1958, 1959) analyses of linear and nonlinear instrumental variables (*see* Instrumental Variables in Statistics and Econometrics). See Ogaki (1993) for a valuable discussion of the practical implementation of *GMM* estimation methods. *GMM* estimators are constructed in terms of a function f that satisfies eqn [1], where f has more coordinates, say n, than there are components to the parameter vector β_o. Another related estimation method is M-estimation. M-estimation is a generalization of maximum likelihood and least squares estimation. M-estimators are typically designed to be less sensitive to specific distributional assumptions (*see* Robustness). These estimators may be depicted as solving a sample counterpart to eqn [1] with a function f that is nonseparable, but with the same number of moment conditions as parameter estimators.

In Sections Linear Models, Models of Financial Markets, and From Densities to Diffusions we will give examples of the construction of the f function, including ones that are not separable in x and β, and ones for which there are more coordinates than parameter vectors. A minimum chi-square-type criterion is often employed in *GMM* estimation. For instance, it is common to define the *GMM* estimator as the solution to

$$b_T = \arg\min_{\beta} Tg_T(\beta)'Vg_T(\beta)$$

where

$$g_T(\beta) = \frac{1}{T}\sum_{t=1}^{T} f(x_t,\beta)$$

and V is a positive definite weighting matrix. This quadratic form has the chi-square property provided that V is an estimator of the inverse of an appropriately chosen covariance matrix, one that accounts for temporal dependence.

The following sections survey some applications of *GMM* estimators to economic time series. A feature of many of these examples is that the parameter β by itself may not admit a full depiction of the stochastic process that generates data. *GMM* estimators are constructed to achieve 'partial' identification of the stochastic evolution and to be robust to the remaining unmodeled components.

Time Series Central Limit Theory

Time series estimation problems must make appropriate adjustments for the serial correlation for the stochastic process $\{f(x_t, \beta_o)\}$. A key input into the large sample properties of *GMM* estimators is a central limit approximation

$$\frac{1}{\sqrt{T}}\sum_{t=1}^{T} f(x_t,\beta_o) \Rightarrow \text{Normal}\,(0,\Sigma_o)$$

for an appropriately chosen covariance matrix $\sum_o$. An early example of such a result was supplied by Gordin (1969), who used martingale approximations for partial sums of stationary, ergodic processes. See Hall and Heyde (1980) for an extensive discussion of this and related results. The matrix $\sum_o$ must include adjustments for temporal dependence:

$$\sum_o = \sum_{j=-\infty}^{+\infty} Ef(x_t,\beta_o)f(x_{t-j},\beta_o)'$$

which is the long-run notion of a covariance matrix that emerges from spectral analysis of time series. In many *GMM* applications, martingale arguments show that the formula for $\sum_o$ simplifies to include only a small number of nonzero terms. It is the adjustment to the covariance matrix that makes the time series implementation differ from the *iid* implementation (Hansen, 1982).

Adapting the minimum chi-square apparatus to this environment requires that we estimate the covariance matrix $\sum_o$. Since f is not typically separable in x and β, an estimator of $\sum_o$ requires an estimator of β_o. This problem is familiar to statisticians and econometricians through construction of feasible generalized least squares estimators. One approach is to form an initial estimator of β_o with an arbitrary nonsingular weighting matrix V and to use the initial estimator of β_o to construct an estimator of $\sum_o$. Hansen (1982), Newey and West (1987), and many others provide consistency results for the estimators of $\sum_o$. Another approach is to iterate back and forth between parameter estimation and weighting matrix estimation until a fixed point is reached, if it exists. A third approach is to construct an estimator of $\sum(\beta)$ and to replace V in the chi-square criterion by an estimator of $\sum(\beta)^{-1}$ constructed for each β. Given the partial specification of the model, it is not possible to construct $\sum(\beta)$ without the use of the time series data. Long-run covariance estimates, however, can be formed for the process $\{f(x_t, \beta)\}$ for each choice of β. Hansen et al. (1996) refer to this method as *GMM* estimation with a continuously updated weighting matrix. Hansen et al. (1996), Newey and Smith (2000), and

Stock and Wright (2000) describe advantages of using continuous updating, and Sargan (1958) shows that in some special circumstances this method reproduces a quasi-maximum likelihood estimator.

Efficiency

Since the parameter vector β that enters moment condition eqn [1] may not fully characterize the data evolution, direct efficiency comparisons of *GMM* estimators with parametric maximum likelihood are either not possible or not interesting. However, efficiency statements can be made for narrower classes of estimators.

For the study of *GMM* efficiency, instead of beginning with a distance formulation, index a family of *GMM* estimators by the moment conditions used in estimation. Specifically study

$$ag_T(b_T) = 0$$

where a is a k by n selection matrix. The selection matrix isolates which (linear combination of) moment conditions will be used in estimation and indexes alternative *GMM* estimators. Estimators with the same selection matrix have the same asymptotic efficiency. Without further normalizations, multiple indices imply the same estimator. Premultiplication of the selection matrix a by a nonsingular matrix e results in the same system of nonlinear equations. In practice, the selection matrix can depend on data or even on the parameter estimator provided that the selection matrix has a probability limit. As with weighting matrices for minimum chi-square criteria, we suppress the possible dependence of the selection matrix a on data or on parameters for notational simplicity. The resulting *GMM* estimators are asymptotically equivalent (to possibly infeasible) estimators in which the selection matrix is replaced by its probability limit. As has been emphasized by Sargan (1958, 1959) in his studies of instrumental variables estimators, estimation accuracy can be studied conveniently as a choice a^* of an efficient selection matrix. The link between a weighting matrix V and selection matrix a is seen in the first-order conditions:

$$a = V\frac{1}{T}\sum_{t=1}^{T}\frac{\partial f(x_t, b_T)}{\partial \beta}$$

or their population counterpart:

$$a = Vd$$

where

$$d = E\left[\frac{\partial f(x_t, \beta_o)}{\partial \beta}\right]$$

Other distance measures including analogs to the ones studied by Berkson (1944) and Taylor (1953) can also be depicted as a selection matrix applied to the sample moment conditions $g_T(\beta)$. Moreover, *GMM* estimators that do not solve a single minimization problem may still be depicted conveniently in terms of selection matrices. For example, see Heckman (1976) and Hansen (1982) for a discussion of recursive estimation problems, which require solving two minimization problems in sequence.

Among the class of estimators indexed by a, the ones with the smallest asymptotic covariance matrix satisfy

$$a = ed'\Sigma_o^{-1}$$

where e is any nonsingular matrix, and the best covariance matrix is $d'(\Sigma_o)^{-1}d$. This may be shown by imitating the proof of the famed Gauss–Markov Theorem, which establishes that the ordinary least squares estimator is the best linear unbiased estimator.

Semiparametric Efficiency

Many *GMM* applications, including ones that we describe subsequently, imply an extensive (infinite) collection of moment conditions. Application of the previous analysis requires an ad hoc choice of focal relations to use in estimation. Hansen (1985) extends this indexation approach to time series problems with an infinite number of moment conditions. The efficiency bound for an infinite family of *GMM* estimators can be related to the efficiency of other estimators using a semiparametric notion of efficiency. A semiparametric notion is appropriate because an infinite-dimensional nuisance parameter is needed to specify fully in the underlying model. It has been employed by Chamberlain (1987) and Hansen (1993) in their study of *GMM* estimators constructed from conditional moment restrictions.

Linear Models

Researchers in econometrics and statistics have long struggled with the idea of how to identify an unknown coefficient vector β_o in a linear model of the form

$$\beta_o \cdot y_t = u_t$$

where y_t is a k-dimensional vector of variables observed by an econometrician. Least squares method solves this problem by calling one of the variables, y_{1t}, the dependent variable and requiring the remaining variables, y_{2t}, to be orthogonal to the disturbance term:

$$E(u_t, y_{2t}) = 0$$

Alternatively, as suggested by Karl Pearson and others, when there is no natural choice of a left-hand side variable, we may identify β_o as the first principal component, the linear combination of y_t with maximal variance subject to the constraint $|\beta| = 1$.

A third identification scheme exploits the time series structure and has an explicit economic motivation. It is a time series analog to the instrumental variables and two-stage least squares estimators familiar to economists. Suppose that a linear combination of y_t cannot be predicted given data sufficiently far back into the past. That is,

$$E(\beta_o \cdot y_t | \mathscr{F}_{t-m}) = 0 \qquad [3]$$

where $\mathscr{F}_t$ is a conditioning information set that contains at least current and past values of y_t. This conditional moment restriction can be used to identify the parameter vector β_o, up to scale. In this setup there may be no single variable to be designated as endogenous with the remainder being

exogenous or even predetermined. Neither least squares nor principal components are appropriate for identifying β_o.

The model or the precise context of the application dictates the choice of lag m. For instance, restriction eqn [3] for a specified value of m follows from martingale pricing relations for multiperiod securities, from Euler equations of the investment problems faced by decision makers, or from the preference horizons of policymakers.

To apply *GMM* to this problem, use eqn [3] to deduce the matrix equation

$$E(Z_{t-m}\gamma_t')\beta_o = 0$$

where z_t is an n-dimensional vector of variables in the conditioning information set $\mathscr{F}_t$ and $n \geq k - 1$. By taking unconditional expectations we see that β_o is in the null space of the n by k matrix $E(Z_{t-m}\gamma_t')$. The model is overidentified if $n \geq k$. In this case the matrix $E(Z_{t-m}\gamma_t')$ must be of reduced rank and in this sense is special. This moment condition may be depicted as in eqn [1] with

$$f(x_t, \beta) = Z_{t-m}\gamma_t'\beta_o$$

where x_t is a vector containing the entries of z_{t-m} and γ_t. The *GMM* test of overidentification, based on say a minimum chi-square objective, aims to detect this reduced rank. The *GMM* estimator of β_o seeks to exploit this reduced rank by approximating the direction of the null space.

For the *GMM* applications in this section and Section Models of Financial Markets, there is a related but independent statistics literature. Godambe and Heyde (1987) and others study efficiency criteria of martingale estimation equations for a fully specified probability model. By contrast, our models are partially specified and have estimation equations, e.g., $\sum_{t=1}^{T}[Z_{t-m}\gamma_t']\beta_o$, that is a martingale only when $m = 1$. When the estimation equation is not a martingale, Hansen (1982, 1985) constructs an alternative martingale approximation to analyze statistical efficiency.

Given that the null space of $Ez_{t-m}\gamma_t'$ is not degenerate, it might have more dimensions than one. While the moment conditions are satisfied (the null space of $E(Z_{t-m}\gamma_t')$ is nondegenerate), the parameter vector itself is underidentified. Recent literature on weak instruments is aimed at blurring the notion of being underidentified. See Stock and Wright (2000) for an analysis of weak instruments in the context of *GMM* estimation.

As posed here the vector β_o is not identified but is at best identified up to scale. This problem is analogous to that of principal component analysis. At best, we might hope to identify a one-dimensional subspace. Perhaps a sensible estimation method should therefore locate a subspace rather than a parameter vector. Normalization should be inessential to the identification beyond mechanically selecting the parameter vector within this subspace. See Hansen et al. (1996) for a discussion of normalization invariant *GMM* estimators. This argument is harder to defend than it might seem at first blush. Prior information about the normalized parameter vector of interest may eliminate interest in an estimation method that is invariant to normalization.

There are some immediate extensions of the previous analysis. The underlying economic model may impose further, possibly nonlinear, restrictions on the linear subspace. Alternatively, the economic model might imply multiple conditional moment relations. Both situations are straightforward to handle. In the case of multiple equations, prior restrictions are needed to distinguish one equation from another, but this identification problem is well studied in the econometrics literature.

Applications

A variety of economic applications produce conditional moment restrictions of the form in eqn [3]. For instance, Hansen and Hodrick (1980) studied the relation between forward exchange rates and future spot rates, where m is the contract horizon. Conditional moment restrictions also appear extensively in the study of a linear-quadratic model of production smoothing and inventories (see West (1995) for a survey of this empirical literature). The first-order or Euler conditions for an optimizing firm may be written as eqn [3] with $m = 2$. Hall (1988) and Hansen and Singleton (1996) also implement linear conditional moment restrictions in the lognormal models of consumption and asset returns. These moment conditions are again derived from first-order conditions, but in this case for a utility-maximizing consumer/investor with access to security markets. Serial correlation due to time aggregation may cause m to be two instead of one. Finally, the linear conditional moment restrictions occur in the literature on monetary policy response functions when the monetary authority is forward looking. Clarida et al. (2000) estimate such models in which m is dictated by preference horizon of the Federal Reserve Bank in targeting nominal interest rates.

Efficiency

The choice of z_{t-m} in applications is typically ad hoc. The one-dimensional conditional moment restriction of eqn [3] actually gives rise to an infinite number of unconditional moment restrictions through the choice of the vector z_{t-m} in the conditioning information set $\mathscr{F}_{t-m}$. Any notion of efficiency based on a preliminary choice z_{t-m} runs the risk of missing some potentially important information about the unknown parameter vector β_o. It is arguably more interesting to examine asymptotic efficiency across an infinite-dimensional family of *GMM* estimators indexed by feasible choices of z_{t-m}. This is the approach adopted by Hansen (1985), Hansen et al. (1988), and West (2001). The efficient *GMM* estimator that emerges from this analysis is infeasible because it depends on details of the time series evolution. West and Wilcox (1996) and Hansen and Singleton (1996) construct feasible counterpart estimators based on approximating the time series evolution needed to construct the efficient z_{t-m}. In particular, West and Wilcox (1996) show important improvements in the efficiency and finite sample performance of the resulting estimators.

Efficient *GMM* estimators based on an infinite number of moment conditions often place an extra burden on the model builder by requiring that a full dynamic model be specified. The cost of misspecification, however, is not so severe. While a mistaken approximation of the dynamics may cause an

efficiency loss, by design it will not undermine the statistical consistency of the *GMM* estimator.

Models of Financial Markets

Models of well-functioning financial markets often take the form

$$E(d_t z_t | \mathscr{F}_{t-m}) = q_{t-m} \qquad [4]$$

where z_t is a vector of asset payoffs at date t, q_{t-m} is a vector of the market prices of those assets at date t, and $\mathscr{F}_t$ is an information set available to economic investors at date t. By assumption, the price vector q_t is included in the information set $\mathscr{F}_t$. The random variable d_t is referred to as a 'stochastic discount factor' between dates $t-m$ and date t. This discount factor varies with states of the world that are realized at date t and encodes risk adjustments in the security market prices. These risk adjustments are present because some states of the world are discounted more than others, which is then reflected in the prices. The existence of such a depiction of asset prices is well known since the work of Harrison and Kreps (1979), and its conditional moment form used here and elsewhere in the empirical asset pricing literature is justified in Hansen and Richard (1987). In asset pricing formula [4], m is the length of the financial contract, the number of time periods between purchase date and payoff date.

An economic model of financial markets is conveniently posed as a specification of the stochastic discount factor d_t. It is frequently modeled parametrically

$$d_t = g(y_t, \beta_o) \qquad [5]$$

where the function g is given a priori but the parameter β_o is unknown, and is a target of estimation. Models of investor preferences may be written in this manner as can observable factor models in which d_t is a function (often linear) or vector y_t of 'factors' observed by an econometrician. See Cochrane (2001), for example, and a discussion of how this approach is connected to other empirical methods in financial economics.

To apply *GMM* estimation, inference, and testing to this problem we do two things. First we replace eqn [4] by its unconditional counterpart

$$E(d_t z_t - q_{t-m}) = 0$$

which can be justified by applying the law of iterated expectations. Second we substitute eqn [5] into this unconditional moment implication

$$E[g(y_t, \beta_o) z_t - q_{t-m}] = 0$$

This may be depicted as eqn [1] by writing

$$f(x_t, \beta) = g(y_t, \beta) z_t - q_{t-m}$$

where x_t contains the entries of the factors y_t, the asset payoffs z_t, and the corresponding prices q_{t-m}. As is evident from Hansen and Singleton (1982) and Kocherlakota (1996), *GMM*-based statistical tests of this model give rise to one characterization of what is commonly termed as the 'equity premium puzzle.' This puzzle is a formal statement of how the observed risk–return trade-off from financial market data is anomalous when viewed through the guises of many standard dynamic equilibrium models from the macroeconomics and finance literatures.

Studying unconditional rather than conditional moment relations may entail a loss of valuable information for estimation and testing. As emphasized by Hansen and Richard (1987), however, information in the set $\mathscr{F}_{t-m}$ may be used by an econometrician to form synthetic payoffs and prices. This information is available at the initiation date of the financial contract. While use of conditioning information to construct synthetic portfolios reduces the distinction between conditional and unconditional moment restrictions, it introduces additional challenges for estimation and inference that are being confronted in ongoing econometric research.

From Densities to Diffusions

A century ago Karl Pearson proposed a family of density functions and a moments-based approach to estimating a parameterized family of densities. The densities within this family have logarithmic derivatives that are the ratio of a first-order to a second-order polynomial. More recently, Wong (1964) provided scalar diffusion models with stationary distributions in the Pearson family. Diffusion models are commonly used in economic dynamics and finance.

A scalar diffusion is a solution to a stochastic differential equation:

$$\mathrm{d}x_t = \mu(x_t)\mathrm{d}t + \sigma(x_t)\mathrm{d}B_t$$

where μ is the local mean or drift for the diffusion, σ^2 is the local variance or diffusion coefficient, and B_t is standard Brownian motion. I now revisit Pearson's estimation problem and method, but in the context of a data generated by a diffusion.

The stationary density q of a diffusion satisfies the integral equation

$$\int_{\underline{r}}^{\overline{r}} \left(\mu\phi + \frac{\sigma^2}{2} \frac{\mathrm{d}\phi}{\mathrm{d}x} \right) q \mathrm{d}x = 0 \qquad [6]$$

for a rich class of ϕ's, referred to as test functions. This gives an extensive family of moment conditions for any candidate (μ, σ^2). In particular, moment conditions of the form eqn [1] may be built by parameterizing μ and σ^2 and by using a vector of test functions ϕ. Pearson's moment recursions are of this form with test functions that are low-order polynomials.

Pearson's method of estimation was criticized by R.A. Fischer because it failed to be efficient for many members of the Pearson family of densities. Pearson and Fischer both presumed that the data generation is *iid*. To attain asymptotic efficiency with *iid* data, linear combinations of $f(x, \beta_o)$ should reproduce the score vector for an implied likelihood function. Low-order polynomials fail to accomplish this for many members of the Pearson family of densities, hence the loss in statistical efficiency.

When the data are generated by a diffusion, the analysis of efficiency is altered in a fundamental way. Parameterize the time series model via $(\mu_\beta, \sigma_\beta^2)$. There is no need for restrict μ and σ^2 to be low-order polynomials. Let Φ be a vector of test functions with at least as many component functions as parameters to estimate. Associated with each Φ is a *GMM* estimator by forming

$$f(x,\beta) = \mu_\beta(x)\Phi(x) + \frac{1}{2}\,\sigma_\beta^2(x)\frac{\mathrm{d}\Phi}{\mathrm{d}x}(x)$$

The moment conditions eqn [1] follow from eqn [6].

Conley et al. (1997) calculate the efficiency bounds for this estimation problem using the method described in Hansen (1985). They perform this calculation under the simplifying fiction that a continuous-data record is available and show that an efficient choice of Φ is

$$\Phi_\beta(x) = \frac{\partial}{\partial\beta}\left[\frac{2\mu_\beta(x) + \mathrm{d}\sigma_\beta^2(x)\big/\mathrm{d}x}{\sigma_\beta^2(x)}\right] \qquad [7]$$

The choice of test function turns out to be the 'derivative' of the score vector with respect to the Markov state x. This efficient choice of Φ depends on the true parameter vector β_o and hence is infeasible to implement. Conley et al. (1997) show that the same efficiency can be attained by a feasible estimator in which Φ is allowed to depend on β as in eqn [7]. The score function derivative is easier to compute than the score function itself because the constant of integration for implied density does not have to be evaluated for each β. While tractable, this efficient test function solution to the time series problem will typically not lead one to use low-order polynomials as test functions even for Pearson's parameterizations.

Pearson used moment recursions to construct tractable density estimates without numerical integration. Computational concerns have subsided, and the diffusion model restricts more than just the stationary density. Transition densities can also be inferred numerically for a given (μ, σ^2) pair. To motivate fitting only the stationary density, a model builder must suppose potential model misspecification in the transition dynamics. One example of this form of misspecification is a subordinated diffusion model used to model financial time series in which calendar time and a more relevant information-based notion of economic time are distinct.

Integral eqn [6] is 'localized' by using smooth test functions that concentrate their mass in the vicinity of given points in the state space. Banon (1978) exploited this insight to produce a nonparametric drift estimator using a locally constant parameterization of μ. Conley et al. (1997) justify a local linear version of the *GMM* test function estimator described in the previous subsection.

Related Approaches

Since around 1990, statisticians have explored empirical likelihood and other related methods. These methods are aimed at fitting empirical data distributions subject to a priori restrictions, including moment restrictions that depend on an unknown parameter. In particular, Qin and Lawless (1994) have shown how to use empirical likelihood methods to estimate parameters from moment restrictions like those given in eqn [1] for *iid* data. While Qin and Lawless (1994) use the statistics literature on estimation equations for motivation, they were apparently unaware of closely related econometrics literature on *GMM* estimation. Baggerly (1998) describes a generalization of the method of empirical likelihood based on the Cressie–Read divergence criterion. Imbens et al. (1998) and Bonnal and Renault (2001) use this generalization to unify the results of Qin and Lawless (1994), Imbens (1997), Kitamura and Stutzer (1997), and others and *GMM* estimation with a continuously updated weighting matrix. (See Newey and Smith (2000) for a related discussion.) Within the *iid* framework, Bonnal and Renault (2001) show that the continuously updated *GMM* estimator is a counterpart to empirical likelihood except that it uses Pearson's χ^2 criterion. The relative entropy or information-based estimation of Imbens (1997) and Kitamura and Stutzer (1997) is of the same type but based on an information criterion of fit for the empirical distribution.

Kitamura and Stutzer (1997) and others use clever blocking approaches for weakly dependent data to adapt these methods to time series estimation problems. Many *GMM* applications imply 'conditional' moment restrictions where the conditioning information is lagged m time periods. Extensions of these empirical distribution methods to accommodate time series 'conditional' moment implications are an important area of research.

Moment Matching Reconsidered

Statistical methods for partially specified models allow researchers to focus an empirical investigation and to understand sources of empirical anomalies. Nevertheless, the construction of fully specified models is required to address many questions of interest to economists such as the effect of hypothetical interventions or policy changes.

Models of economic dynamical systems remain highly stylized, however; and they are not rich enough empirically to confront a full array of empirical inputs. Producing interesting comparative dynamic results for even highly stylized dynamic systems is often difficult, if not impossible, without limiting substantially the range of parameter values that are considered. Since analytical solutions are typically not feasible, computational methods are required. As in other disciplines, this has led researchers to seek ways to calibrate models based on at least some empirical inputs. See Hansen and Heckman (1996) for a discussion of this literature. The analysis of dynamical economic systems brings to the forefront both computational and conceptual problems.

The computational problems are reminiscent to those confronted by the inventors of minimum chi-square methods. Two clever and valuable estimation methods closely related to moment matching have recently emerged from the econometrics literature. One method is called 'indirect

inference' and has been advanced by Smith (1993) and Gourieroux et al. (1993). The idea is to fit a conveniently chosen, but misspecified approximating model that is easy to estimate. The empirical estimates from the approximating model are used as targets for the estimation of the dynamic economic model. These targets are 'matched' using a minimum chi-square criteria.

This method is sometimes difficult to implement because the implied approximating models associated with the dynamic economic model of interest may be hard to compute. Gallant and Tauchen (1996) circumvent this difficulty by using the score function for the approximating model (evaluated at the empirical estimates) as targets of estimation. The computational burden is reduced to evaluating an empirical score expectation as a function of the underlying parameter of interest. This allows researchers to use an expanded set of approximating statistical models.

In both of these methods there are two models in play, an approximating statistical model and an underlying economic model. These methods address some of the computational hurdles in constructing parameter estimators through their use of convenient approximating statistical models. On the other hand, it is harder to defend their use when underlying dynamic economic model is itself misspecified. Gallant and Tauchen (1996), for instance, use statistical efficiency as their guide in choosing approximating statistical models. Better approximating models result in more accurate estimators of the parameters of interest. This justification, however, neglects the role of misspecification in the underlying dynamic economic model. For 'indirect inference' it is often not evident how to construct approximating models that leave the estimates immune to the stylized nature of the underlying economic model. Thus, it remains an important challenge for econometricians to devise methods for infusing empirical credibility into 'highly stylized' models of dynamical economic systems. Dismissing this problem through advocating only the analysis of more complicated 'empirically realistic' models will likely leave econometrics and statistics on the periphery of important applied research. Numerical characterizations of highly stylized models will continue with or without the aid of statistics and econometrics.

Methodological Individualism in Sociology

Emmanuel Picavet, Université Paris-I Panthéon-Sorbonne, Paris, France

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Methodological individualism in sociology is a family of methodological strategies that portray human agents, their actions, and their interaction as key ingredients of social explanation. Insofar as social phenomena are the results of individual actions, methodological individualism supports a practice of sociology which concentrates on individual motivations of various kinds. This often suggests the use of decision-theoretic methods which are used in other disciplines as well, with possible benefits for interdisciplinary cooperation. Methodological individualism raises problems with respect to the different levels of social explanation (or understanding).

Methodological individualism in sociology refers to explanatory and modeling strategies in which human individuals (with their motivations) and human actions (with their causes or reasons) are given a prominent role in explanations and models. Social phenomena are viewed as the aggregate results of individual actions. Explanation takes its origin in the parts rather than the whole: individual action is invested with explanatory primacy in relation to social facts, society's properties, and observed statistical regularities. Among the problems associated with this methodology, the following three are of special interest: How should individual characteristics be selected and connected? Is the relevance of individualism as a methodology grounded in social ontology, or is it primarily dependent on the known explanatory or predictive benefits to be gained from the use of a family of models and theories? How should individualistic social science take individual and social cognition into account?

Individualism and the Form of Explanations

Giving Primacy to Individuals

While the constitution of sociology as an autonomous discipline has involved the recognition of a separate layer of 'social facts,' methodological individualism, which presupposes the existence of social facts as an *explanandum* for social science, is not alien to the sociological tradition, as exemplified by the work of Weber, Pareto, and others. A general feature of individualistic explanations is that individual motivations, preferences, reasons, propensities, or characteristics generally speaking figure explicitly in the proposed models and explanations, together with the description of relevant technological and natural circumstances.

Methodological individualism has gained influence in the twentieth century through the work of such authors as Mises, Popper, and Hayek, who associated it with liberal views (in different versions). Within the limits of explanatory or predictive social science, its emergence is traceable to the debates in nineteenth-century Germany and Austria about the nature of explanation in history, the status of economic theory, and the respective scientific roles of nomological explanation (a kind of explanation of social facts that makes use of general laws) and contextual understanding. It is classically associated with the requirement of a real understanding of the motivations, intentions, or objectives of the social actors themselves (as illustrated by Simmel, 1900; Weber, 1922). It has made it possible to explore, after Adam Smith, the unintended consequences of individual intentional actions (Cherkaoui, 2006), thus contributing to revealing the complexity of the social world in connection with human action. This is exemplified by the systematic study of the emergence of unplanned norms (Opp, 2001), or conventions and social institutions (Mantzavinos, 2008).

This methodology can be contrasted with several types of nonindividualistic methods (Boyer, 1992). It is violated by those theories which rely on the operation of impersonal forces (such as nature, mind, history, progress, and destiny) or unconscious forces and by 'holistic' explanations in which the properties of collective entities (such as nations, classes, social groups, or society as a whole) are given an independent explanatory role. This opposition refers to explanatory strategies, and it should not be used to oppose two kinds of social science.

Indeed, social scientists who want to be faithful to methodological individualism may well recognize (after Pareto, 1905) that the 'individual' is social to the core, if only because thought and action are intimately related to social realities such as a language, laws, custom, and the like. Culture, education, and traditions give shape to human desires, beliefs, and dispositions, which can be expressed in a shared language and recognized in interpersonal relationships, mutual expectations, and social norms. Following the Paretian methodology, the 'social' is not to be confused with our preferred representations of society as we like it. In particular, the 'social' dimension of social life should not be described by referring to features of a desired society such as solidarity, equality, cohesiveness, social harmony, and so on. Moreover, we should take care not to equate the 'social' with widespread feelings.

On the normative or prescriptive side, the 'social' dimension as Pareto thinks of it must be reconstructed in a problematic way: Are we really able to speak on behalf of 'society' at large? This makes sense when there is a unanimous agreement. If there is no agreement, however, it is deeply objectionable. It amounts to giving primacy to the abstract notion of 'society,' possibly at the expense of concrete, living individuals (especially those who do not belong to majorities).

The other way around, those sociologists who attempt to develop explanations of social facts on the basis of properties of social life are not automatically blind to the social importance of a proper methodological treatment of individuals. They may find it necessary to explore the social determination of 'personal' characteristics. In addition, they may acknowledge the fact that complex individual operations are involved in the processes through which causality flows from social characteristics to particular social events.

In Durkheim's thought, society and the individual have a complex relationship, and Durkheimian 'holism' is a subtle one: social cooperation is a source of empowerment for individuals, but, as cooperation grows (with the concomitant evolution in goals), society becomes a source of impersonal constraints which limit the expression of particularity (Demeulenaere, 2003, ch. 2). Following Boudon's reading of Durkheim (Boudon, 2000, ch. 2), the commitment to explaining features of society as a *sui generis* entity should not mislead us: the sociologist stresses that society is made of individuals, and his or her explanation of collective beliefs (such as religious beliefs) relies on a theory of individual initiatives or activities which result in shared representations. The underlying process is a process of innovation, selection, and retention. Whenever we say that beliefs and languages originate in 'society,' following this reading of Durkheim, this is really shorthand for a more complex theory in which personal initiatives have a major role, even though we do not know the details of individual actions.

Methodological individualism is compatible with ontological holism about collective entities, in the following sense: social scientists who support the methodology may recognize the existence of social entities (such as 'cultures' or 'traditions') which are irreducible to individual component parts. But they postulate that only individuals have goals and interests, and that these have explanatory value with respect to human conduct. They interpret the notion of collective belief in such a way that it cannot be equated with society's thought (e.g., an individualistic interpretation of the notion might involve shared beliefs and the common knowledge of shared beliefs).

Finally, supporters of methodological individualism recognize that the social setup can be transformed through the action of individuals. This makes the methodology hardly compatible with the more deterministic versions of historical materialism. Supporters of the methodology also occasionally reject the culturalist tendency to equate social norms with binding traditions or habits, because they find it useful to start from the notion that social norms are effective only through personal commitment.

The admissibility of group-based concepts in individualistic explanations can be illustrated by the status of identities in sociological knowledge. As stated by Laitin (1998, p. 21), "identity groups have an impressive power to give their adherents a sense of natural membership," but individuals have an "equally impressive power […] to reconstruct their social identities." In this dialectic, the transformative power of individuals connects with the influence of collective entities. Moreover, the social identities play a role in mutual expectations, hence also in the individual choices that are conditional on these expectations. Thus, if individuals have a real power to shape and reshape their social (usually multiple) identities, their initiative affects the social framework of their interaction with other individuals.

Individual Motivation

Some individual characteristics should figure in the *explanans* part of scientific explanations in an explicit manner. But which are the relevant ones? The selection should allow the theorist to reconstruct some basic facts about the choices of reasoning agents, and formulate those relationships which are considered useful for explanation or prediction. Both cognitive factors (such as beliefs or probability judgments) and volitional ones (desires or preferences concerning states of affairs) play a decisive role. There is some uncertainty, however, in the determination of the appropriate concepts of beliefs and preferences. In particular, should they be revealed by introspection, or in actual choice?

Behaviorist social scientists insist that they should be inferred from actual choices (as in revealed preference theory in microeconomics), but most social scientists hypothesize in a bolder way. In particular, the Popperian version of methodological individualism emphasizes the crucial importance of a reconstruction of the knowledge available to the agents themselves. Elucidation of this situation-relative knowledge gives the social scientist a clue to the appropriate beliefs and behaviors of the actors (Watkins, 1970; Popper, 1972, 1976).

If we turn to the goals of the actors: should their preferences be confined to (narrowly conceived) self-interest, for example a combination of pleasures across time? This would be empirically unconvincing. It is then tempting to distinguish several types of action: self-interested action and action out of respect for norms or values, for example. But such a contrast is rather uncertain in many empirical situations. Correlatively, it appears difficult to disentangle the economic dimension from other aspects of human action (Demeulenaere, 1996).

Rationality Hypotheses and Equilibrium

Should the social scientist consider any kind of beliefs, desires, and choices? It would seem awkward to leave unused our knowledge about rational action. Several criteria of rational choice can be used. In the general sense, rationality is the disposition to let one's judgment or action be determined by the best existing reasons or argument. Cognitive rationality is ordinarily viewed as deeply different from practical rationality, even though both of them are involved in the 'rational choice' view of the social sciences. One basic requirement is the existence of a complete and transitive ranking of social states of affairs which, combined with beliefs about uncertain events, yields a ranking of actions. More specialized criteria involve specific relationships between beliefs and evaluative judgments, as exemplified by the classical expected utility formula for choice under risk or uncertainty.

It can hardly be assumed that flesh-and-blood individuals are perfect optimizing entities in all circumstances: given the drastic limitations on our information-processing capabilities, the bounded rationality assumption is more realistic (Simon, 1982), and it should be supplemented by a precise analysis of the complex relationships between intentions, beliefs and

expectations, background knowledge, and representations of the social interaction (Roy, 2008). In many models, agents seem to be confined to single-exit situations: individual goals and the characteristics of the situation are the important explanatory inputs (Latsis, 1972). In most real-world cases, however, individual attitudes in the gathering and use of incomplete knowledge are crucial explanatory factors. In Simon's words, a shift is needed from substantive to procedural rationality. This shift in emphasis has been a decisive factor of scientific progress in recent decades, especially for advances in the understanding of institutional or organizational behavior.

This psychological orientation, however, could be (and has been) resisted for the following reason: sociological explanations of aggregate social facts are not supposed to capture all the details of the actions of existing individuals, but only the central tendencies, among which we should undoubtedly rank the tendency to act rationally through the selection of appropriate means in a purposeful manner (Goldthorpe, 1998). It can thus be argued that sociology, as part of empirical science, should neither restrict itself to the elucidation of the logical consequences of the interaction of ideally rational agents, nor try to replicate the psychological functionings of particular agents. As it turns out, sociology often relies on ordinary psychology (Boudon, 2006, ch. 7, argues that this is a valuable part of Tocqueville's heritage in sociology).

Classical sociology exemplifies the tension between the tendency to rely on psychological facts or mechanisms and the appreciation of the specificity of social facts and sociological explanation. A notable example is Gabriel Tarde's notion of 'psychological statistics,' and his determination to analyze decision making in social settings, trying to make use of a direct description (or measurement) of personal characteristics such as desire and belief, and contemplating a generalization of the psychophysical line of inquiry with the aim of developing social explanations. In practice, sociologists can hardly focus on social situations exclusively or psychological processes exclusively. Stylized models of both are required, and an important problem of the micro–macro linkage consists in determining the appropriate kind of stylized description of facts or processes at the microlevel. A complex treatment of psychological processes seems required in some cases, and this provides opportunities for interdisciplinary work. The two imperatives of psychological relevance and situational analysis are complementary in a deep sense, since the rational agent's *adaptive* cognitive strategy in the face of incomplete *knowledge* must depend on the characteristics of his or her incomplete-knowledge situation.

In most social contexts, the reasons for action of distinct individuals are clearly not independent from one another, and the hypothesized relationships between individual preferences, beliefs, and actions assume the form of an equilibrium, that is to say, a pattern of correlated choices of actions among individuals in a given group or society. In economics, the concept mainly refers to a state of equality between supply and demand; other concepts have been developed and applied in modeling. In game theory, an 'equilibrium' is a situation in which individual actions are mutually adjusted in an understandable sense (e.g., as best answers to one another, as in the 'Nash equilibrium' concept). The importance of this kind of approach was neatly brought out in Cournot's analysis of imperfect economic competition. In the definition of equilibrium concepts, the interrelationships between the predicted social facts and individual reasoning are made clear. In some cases, however, the predictive value of equilibrium concepts (such as the 'Nash equilibrium,' in which each agent's action is the best response to the actions of others) presupposes a fairly sophisticated coordination mechanism for individual expectations, or even sociologically or culturally determined common focal points. This suggests that some preexisting 'social' facts, such as cultural conventions, categories of the language, and accepted attitudes, might have independent explanatory value after all (Janssen, 1997).

Individualistic Descriptions and the Uses of Social Theory

Models and theories are used in several ways. How does this plurality affect the significance of methodological individualism and the relevance of individual-based descriptions? The relationship between positive and normative uses of theories should be considered. Of equal importance is the level of description at which theory-based inferences and predictions are formulated.

The Individualistic Point of View and Normative Thinking

Scientific commitment to methodological individualism for explanatory purposes should not be mixed up with the presumption that individuals give no weight to other people in their own choices. In particular, as Popper noted, an individualistic understanding of social life need not lead to underrating the importance or value of altruistic feelings or nonselfish interests generally speaking: "What really matters are human individuals, but I do not take this to mean that it is I who matter very much" (Popper, 1962). Methodological individualism is an invitation to study, from the point of view of the individual, the balance between self-centered interests and the importance given to the interests or values of other people, as well as institutional commitments. This balance is, in itself, an object of inquiry for normative thinking insofar as we can influence the relative weights of these different kinds of interests for practical purposes.

A number of important normative criteria presuppose an individualistic description of social life. For example, the usual criteria associated with freedom and responsibility have no clear significance unless social life is understood with a view to the causal powers of persons, portrayed as autonomous units in decision-making tasks. These units must be thought of as capable of self-consciousness, evaluation, deliberative choice, and action. It thus appears that common normative views about social life or institutions implicitly rely on an individualistic kind of description and explanation with respect to social phenomena and personal capacities.

According to Baechler (2006, ch. 6), the social agent's freedom consists of choice among possible alternatives, insofar as autonomous deliberation takes place, in a way that testifies to rectitude and rightness. This statement sums up a family of

interrelated arguments and theses that have often been put forward in the tradition of methodological individualism in sociology, with the general intention of making it clear that the transformative powers of the individual in social life are ultimately grounded in the individual's capacity for autonomous choice. The latter capacity is best expressed in freedom of choice as expressed in social settings which provide opportunities to give one's consent to collective, interpersonal, or impersonal constraints.

At a fundamental level, some kind of individualistic description of social life is involved in the formulation of many evaluative criteria. In most cases, equality or efficiency criteria can be applied only if we are able to ascertain that definite states of affairs are experienced by distinct individuals. Individualism, here, stands for an 'atomistic' understanding of social life that identifies the separate lives and experiences of the individuals (rather than collective entities) as the *loci* at which things of value are to be found.

The understanding of individual action in a social environment matters for normative issues in the treatment of communities and groups. Cultural and religious communities, for example, are made of individuals. Consequently, the different kinds of involvement of communities in public life are deeply affected by the status enjoyed by individuals: their status in the political structure as well as in the more specific communities. Under liberal rule, we are equipped with rights, and the key issues about liberal political communities today connect with the nature of exercising personal rights in the political community at large. Representations of (possibly oppressive or coercive) interpersonal ties in the communities matter in this respect, with the methodological consequence that the sociological dimension of exercising rights cannot be ignored by normative theory when it addresses dilemmas about the treatment of groups in society at large.

Ballet et al. (2007) have stressed that the capability approach in social science and philosophy recognizes the importance of "connections between people, through their social commitments and their embedding in social institutions" (p. 186). From this viewpoint, it is quite clear that assessing the value of the exercising of rights or freedoms makes it necessary to refer to cultural and ethical standards, such as fairness standards. These authors have further argued that social links, expectations, and commitments account for the role of fairness standards in exercising rights. As a result, due attention to the capacity for justified self-imposed constraint is credited with delivering a 'stronger vision of agency.'

Individualism and the Levels of Description of Complex Social Facts

Several types of explanation might appear relevant and informative at different levels of description. The projected inferential and predictive uses of social theory are thus decisive for the relevance of individual-based descriptions and explanations of social life. As a matter of fact, the very notion of sociology as a separate discipline is sometimes understood in a holistic manner because sociology is supposed to describe and explain complex 'social facts' which cannot be described and explained adequately at the microlevel of individual action and interindividual interaction.

In Durkheim's classic study of suicide, for example, human conduct is understood on the basis of the social characteristics that account for the scientifically relevant aggregate facts. The propensities for suicide can be explained only by referring to the state of social groups, in particular their characteristics with respect to the integration of individuals. The statistical facts about the frequency of individual actions are explained by social properties.

The holistic dimension in Durkheimian sociology lies in a belief in the independent explanatory value of 'macro' notions with respect to observed individual conduct. If we turn to rules and institutions, this means that individual agreements cannot be treated as independent explanatory factors. In the tradition of methodological individualism, however, theorists try to explain rules and institutions by focusing on the circumstances of individual rational choice (as in Olson, 1965; Coleman, 1990).

Social explanations in the spirit of Durkheim can be reinterpreted in individualistic or interactionist terms to some extent, by focusing on the psychological dimension of complex microsociological patterns of interdependencies that aggregate into macro properties such as social integration, cohesiveness of groups, and so on. Given the parallelism between the two levels of description, the choice between an individualistic perspective and a holistic one should be considered in the light of the projected use of theory: do we intend to describe macrophenomena, or do we try to understand microinteractions and their aggregate effects? The relevance of methodological individualism is clearer in the second case.

Correlated descriptions of individual and social situations also matter in action-oriented social research. Following 'softsystems methodology,' for example (in the field of problem-structuring methods for group choice), we are invited to acknowledge that accounts of purposeful action are 'given in terms of an interpretation applied by the speaker' (Checkland, 2001); given the importance of biases and alternative value systems, we should accept a multiplicity of descriptions of purposeful activities. Accordingly, a model of human action that is used analytically for the purposes of group choice should make its underlying *Weltanschauung* explicit, in order to make sure that the descriptions are meaningful.

Individual Cognition and Sociological Knowledge

Reasons and Cognitive Processes

Individuals are reasoning entities: they develop elaborate cognitive structures – even social theories – about their own action and interaction. How should individualistic social science take this into account? Arguably, rational action involves cognitive operations to some extent. This is true of instrumentally rational actions, after the pattern of 'logical actions' in Pareto's sense, since the adequate association of ends and means is possible only on the basis of some representation of the world and some reasoning about it. 'Maximization' refers to the modeling of individual behavior as the constrained optimization of an objective function. An alternative approach consists in the choice of best elements in opportunity sets, given the preferences of the

considered agents. Methodological individualism in the social sciences has led to an extensive use of optimization programs for modeling purposes.

Sometimes, the goal and its causal association with the available means are obvious, so that the cognitive process will not figure prominently in the proposed explanations. In other cases, the interesting part of the explanation is the cognitive process itself. Strategic situations are a clear example. As Roy (2008, sec. 3.3) puts it, rational choice in strategic games is "a matter of maximizing expected payoffs given what the agents expect each other to do"; relying on hypotheses of rationality in games then obliges the scientist to take mutual expectations into account, and this yields an array of game-theoretic 'solution' concepts for strategic situations. Cognition, here, is at the core of social knowledge insofar as game-theoretic 'solutions' are used to predict or explain interactive behavior among human agents.

The explicit treatment of this cognitive dimension appears to be the best response to the critique according to which individualistic models rely on an arbitrarily simplified account of human action as instrumentally rational action. It is useless to deny the importance of instrumental, means-end reasoning in social interaction. But much is to be gained by paying attention to the cognitive processes through which agents frame their choices (Fillieule, 1996). Cognitive sociologists also explore the inner logic of argumentative strategies (Boudon, 1990; Bouvier, 1999). A challenging dimension of the theorist's work is to reconstruct the intrinsically convincing reasons which are intermingled with mistaken beliefs, resulting in seemingly irrational behavior.

Of particular interest are the processes through which individual agents evaluate and adjust their own goals, and select the norms of behavior they are willing to accept as binding. Processes of this kind cannot be left aside in sociological inquiries that rely on a broad notion of rationality, understood as acting on the best reasons and, accordingly, pursuing appropriate goals through effective means (or, more generally, making the best choices in the light of appropriate values and objectives). This was already exemplified in the classical Weberian notion of axiological rationality, now reinterpreted within the framework of theories of cognitive rationality (Boudon, 1995, 1998; Mesure, 1998; Saint-Sernin et al., 1998).

This implies that rationality requirements are also relevant for the actor's goals, beyond the instrumental adequacy of the means to the goal; these requirements may differ from the criteria of means-end or utility-maximizing adequacy (in utilitarian philosophies and in economic theory, 'utility' is the synthetic goal of an agent who seeks to get maximum satisfaction as a result of his or her action, and in the case of choices under risk or uncertainty, 'expected utility' gives insights about the average consequences of risky choices). This methodological choice is not consensual; it is motivated by an effort to gain a better fit between theoretical predictions and observed social facts. For instance, a long-standing puzzle in individualistic political studies is the so-called paradox of not voting: since individual voting in general elections has small disadvantages and no clear causal effect, why do people vote? A particular line of individualistic inquiry starts from the hypothesis that most people are able to understand the basic reasons that support the following general normative statement 'Citizens should vote.'

Cognition and the Levels of Description

Explicit treatment of individual cognition is a valuable goal, and the sociologist's concern with representations is a motive for modeling the variations of social representations among individuals (Balzer, 1993, ch. 7). Useful theories of individual cognition in social science raise questions about how precisely to draw the dividing lines between the building blocks of individualistic sociological explanation: between individual characteristics and natural facts on the one hand, and between individual characteristics and the relationship between them on the other hand. For example, choice theory as social scientists think of it should be a theory of the relevant individual characteristics, such as desires, intentions, beliefs, and so on. The comparative intensity of desire for goods or states of affairs is a proper object of scrutiny. But should the relevant individual characteristics be borrowed (for modeling purposes) from psychological or biological knowledge about the natural facts of feeling and sensation? In addition, individual characteristics which seem to be relevant for understanding individual choice, such as the comparative strength of preference, have sometimes been thought to be best understood in connection with other individual characteristics, such as the association of pleasure and pain (and their degrees) with goods or states of affairs (Hands, 2006, has analyzed the strategic situation in such debates of the doctrine of cardinalism – a view of welfare or utility according to which these notions can be given quantitative meaning in the sense that ratios between utility (or welfare) differences are considered meaningful statements).

At some level of description, individual action is made of a series of natural (neural and external) states of affairs. It thus appears that individual 'good reasons' can be screened off by the natural causes of behavior, which are a proper object of inquiry for natural science, and methodological individualism in its classical versions might appear misleading insofar as it treats individual good reasons as the ultimate explanations of action. Psychological processes are implemented in the human brain by neuronal functionings, but this does not imply that the 'ultimate' explanation of social phenomena is to be found at the neurophysiological level or at the molecular level.

Science is constructed in layers, in such a manner that it includes both higher level theories which work at the macro-level appropriate to the macrophenomena to be explained (such as mainstream sociological theories) and other theories which show how the higher level objects and relations can be explained through scientific work at the level below (Simon, 1997). The hierarchical relationship between two classes of phenomena does not automatically imply that explanation should proceed from the lower level to the higher level.

At a certain level of description, individual action is the sequel of an intention which can be described only in a certain language, using definite mental categories. Arguably, language, categories, and meanings are social objects. Hence, it might appear appropriate to consider human actions as understandable only on the basis of preexisting rules, or

'institutions' in Mauss's sense, which social actors find before them as preexisting facts. Indeed, social norms have a constitutive role with respect to the meaning of actions – undoubtedly an important feature of many social situations. This is not automatically alien to individualistic explanations, if we allow for psychological motives which depend on complex, holistic representations of social interaction, along the lines of institutional individualism (Agassi, 1975). As a matter of fact, most social rules are not just given as 'facts' but also are agreed upon, or rejected, by individuals.

Individualistic explanatory and predictive strategies in sociology rely on a sharp distinction between the choice problems of individual actors, on the one hand, and social institutions, regularities, and norms, on the other hand. On this account, the emergence and stability of social regularities, social norms, and institutions should be explained on the basis of the underlying individual reasons. This creates opportunities for the use of both classical rational-choice models and elaborate theories of individual cognition.

This article is a revision of the previous article by G. Currie, volume 5, pp. 9755–9760, © 2001, Elsevier Ltd.

Abstract

Methodological individualism is a central tradition in the social sciences. The article argues that it corresponds to one main thesis, which is that only individuals act in the social life. The article examines the consequences that can be deduced from this main proposition regarding the theory of behavior and explanation in the social sciences, and also examines the misunderstandings to which it frequently leads.

Introduction

Methodological individualism (MI) is a central tradition in the social sciences. It is a theory about human agency in a social world and about the articulation of the various entities constituting such a world. It is consequently a theory of explanation of social phenomena.

The main idea that can characterize MI is that, in social life, so-called social entities do not act by themselves, only individuals (i.e., human beings) do so. Philosophers and social scientists such as John Stuart Mill, Carl Menger, and Max Weber initially deployed this basic idea, although none of them directly used the term 'methodological individualism.' However, a close expression can be found in Weber's analysis. Schumpeter coined the term. Popper and his followers, notably Watkins, developed the notion in a more philosophical way. Many other singular theorists have been associated with the movement. At the discipline level, economics is generally associated with MI, whereas sociology is more divided regarding this issue, with the intervention of holism or methodological holism.

Because only individuals can act, methodological individualists consider that social entities (like states, institutions, organizations) do not act by themselves but need individuals to be set in motion. This rather simple idea is, however, compatible with two other major propositions. First, institutions and social entities can, under certain conditions, be assimilated to actors. However, in the tradition of MI, it remains that such corporate actors need individuals to be set in motion. Second, social entities can have an 'influence' on individual behaviors, although this notion of influence can be interpreted in various ways. It depends mainly on the nature of the social entities that are taken into consideration. In this article, it is not possible to present the details of each author's positions. Therefore I will try to present the logical consequences of the main idea developed by MI, that only individuals act.

If we set aside the difficult problem of animal behavior, which I will not address here, it can be said that in social life only individuals act. This is clearly stated by Max Weber:

> Action in the sense of subjectively understandable orientation of behavior exists only as the behavior of one or more *individual* human beings. (Weber, 1978: p. 13)

> For still other cognitive purposes – for instance, juristic ones – or for practical ends, it may on the other hand be convenient or even indispensable to treat social collectivities, such as states, associations, business corporations, foundations, as if they were individuals persons. Thus they may be treated as the subjects of rights and duties or as the performers of legally significant actions. But for the subjective interpretation of action in sociological work these collectivities must be treated as solely the resultants and modes of organization of the particular acts of individual persons, since these alone can be treated as agents in a course of subjectively understandable action. (Weber, 1978: p. 13)

This is the fundamental proposition of MI. It means that there is an active social life only because there are individuals who act. It is a descriptive proposition about what is responsible for action in social life. It is not directly an ontological proposition about the existence of individuals or social facts, nor is it a position about explanatory possibilities in the social sciences, although this fundamental proposition has important consequences regarding those matters.

Once said that only individuals act, seven questions derive from this elementary proposition:

1. What does an individual action mean exactly? Does it imply that individuals are separated from each other and do not interact?
2. Does this mean that they are supposed to act in a certain way (a selfish or individualistic way, for instance)?
3. In particular, are individuals supposed to be rational?
4. Does this imply that they are not influenced by institutions and by social settings in the course of their action?
5. Does this exclude an infra-individual description of action?
6. Does the assertion that only individuals act imply that only individuals exist?
7. Does the assertion that only individuals act imply that any explanation of the macro level should be only based on the micro level?

Although MI is frequently associated with positive answers to these questions, I will argue that this should not be the case, both from a logical viewpoint derived from the main MI proposition and from a historical perspective based on the writings of the preeminent authors influential in this tradition.

Interaction

Stressing the uniqueness of individuals as the sole possible actors in the social world does not, however, imply any kind of 'individualistic' position, as Weber clearly insisted on. MI is frequently associated with neoclassical economics in which social outcomes (like market price equilibrium) are derived from separate individual decisions. In this scenario, individuals are separated from each other since, in the model, the formation of price equilibrium does not require their formal agreement. Moreover, in the economic tradition, individuals not only do not cooperate and do not converse in order to produce equilibrium prices, but are selfish: they try to achieve a maximization of their personal utility. These hypotheses are at the core of economic hypotheses. They can be found equally in the theory of games, where actors similarly do not cooperate, in the sense that they do not discuss together the situation and the way to deal with it, and do not initially have a cooperative attitude. On the basis of such behaviors, specific social outcomes can be seen to emerge under certain conditions: for example, price equilibrium or social norms.

However, those two dimensions (absence of direct interaction and selfishness) are not intrinsically necessary to methodological individualism as such, either in theory or in practice. The idea that only individuals act has no logical implication on the nature of their relationships: they can indeed interact and deliberately cooperate and tend to produce social outcomes. They can also have altruistic behaviors. Sociologists have frequently negatively considered methodological individualism as an 'atomism' involving separate actors, who are moreover selfish. But this is not necessarily the case. It is true that Menger (1996) referred to atomism, insisting for instance that money, when it emerges as a social institution, does not need to be the result of an agreement between actors. It derives as an unintended consequence from separate 'atomistic' decisions.

Generally speaking, it can be useful, sufficient, or relevant in specific social situations to suppose that actors act separately and do not cooperate. This is the case, for example, in the stock exchange, or more generally in the ideally conceived markets of neoclassical economics. It can be shown, moreover, that in certain theoretical types of situations (particularly prisoner's dilemma situations), separate selfish individuals can be led to adopt cooperative norms in order to satisfy their interests. But this does not mean that all norms derive from such situations and such behaviors. This type of description corresponds to the fact that in many social situations, individuals in effect do act separately, and moreover in a selfish way. On the basis of such descriptions, we can have the elements from which to derive social outcomes.

But the idea that only individuals act does certainly not imply that it is always the case that individuals do not interact or act in a selfish manner. Interaction can be found in economics, based on selfish motives, when for instance actors set up monopolies or oligopolies. This is clearly the result of an interaction among individuals. Therefore, the specific economic tradition that displays separate actors is not to be conflated (1) with the whole of economic analysis and (2) with MI.

Selfishness and Altruism

As has already been suggested, the idea that only individuals act does not imply that they act in a selfish manner. When J.S. Mill (1988), against the tradition of Comte, insisted on the importance of social phenomena to be based on the action of individuals, and stressed the importance, for economics, to suppose a selfish behavior, defining the *Homo economicus* figure (although he did not use the term), he certainly did not conclude that all men in all circumstances acted in a selfish manner aimed at increasing wealth. On the contrary, he clearly stressed the possibility of moral and altruistic behaviors.

However, MI is frequently reduced to an economic analysis of selfish behavior. Once again this cannot be derived from the core idea that only individuals act. Moreover, the very idea of selfishness and of satisfaction of interests is relatively ambiguous in the economic tradition of action. On the one hand, starting with Mill, the figure of a narrowly defined economic man pursuing the increase of his wealth is designed in order to analyze economic markets. But on the other hand, very soon, the complexity of interests, the variety of preferences, and the fact that the notion of utility is a fundamentally vague one became preponderant in economic analysis: utility depends on various psychological patterns on the one hand and on social norms on the other. Therefore, Pareto first introduced the notion of ophelimity (utility based on individuals' choices), and afterward utility in economics became a formal notion derived from preferences. Preferences are diverse and can be linked to social norms. For instance, smoking or taking drugs can be seen favorably or unfavorably on the basis of personal tastes or social prescriptions. There is, therefore, no intrinsic notion of cost or benefit that is at the bottom of the decision. The decision is itself what allows us to speak of costs or benefits, and they can be diverse for different persons: for one it is costly to take drugs (e.g., to drink alcohol) while for another it is costly not to take them. Therefore, in the domain of economics, the theory of action linked to MI is fundamentally ambiguous: it rests on the idea that actors tend to maximize their benefits or minimize their costs, but because costs and benefits do not represent an unambiguous signification, the theory of action is not really predictive of effective or definite actions and choices (Sen, 1977).

Therefore, the distance between an economic model of social behavior and a sociological model of behavior is strongly reduced (Akerlof and Kranton, 2010). Sociologists have generally attacked methodological individualism on two grounds: (1) the idea that individuals are not selfish persons acting on the basis of a pure calculus of selfish interests and (2) that individuals do not act in a social vacuum but depend on social norms and institutions. This second aspect will be more fully developed next in this article. But it should be clearly noted that those two critiques do not attain the core of the idea of methodological individualism; moreover, they do not attain the core of the economic version itself of methodological individualism, because interests, preferences, and choices can rest on social norms: therefore, social aspects can be found in the very heart of economic decisions, and the question is whether there is or not a theory of decision devoid of any social aspect, in particular of social norms.

Rationality of Action

This leads to another related question: should the theory of individual decisions be taken from a naturalistic stance, where the elements of the decision precede social dimensions, or should it be considered as inherently social, in the sense that there would be no natural, stable, and transcultural regularities in the determinants of the choices beyond the observed social and cultural variety in behaviors? This question is related to the scope and significance of rationality, which can be seen as a natural feature of the human species. However, the idea of rationality is a multisided one, and can be related to each of theses three positions. The idea that only individuals act has by itself no logical consequence regarding the question of cultural and social variation. Three positions are compatible with the core idea: one that would stress that all behaviors depend on a natural (namely psychological) basis, rational or not; another that would insist on the cultural dimension of all individual behaviors, or the social position of the actors; and finally, one that would consider that the two dimensions are always interconnected: the natural features of the human species lead to a diversity of social and cultural situations; this diversity, though real and decisive for individual decisions, is not, however, disconnected from the general natural traits of human behavior, and should tentatively be interpreted in their terms. It is likely that this third option is the right one (Haidt, 2012), and it is linked either to a theory of rationality or to unconscious motives.

Thus the debate about the rationality of action intervenes in the more general frame of the characterization of action and behavior. Methodological individualism is largely linked to (and criticized for) the idea that individuals act in a rational way. But here again, there is no necessary link between the idea of individual action and of rational action. It is perfectly understandable that individuals can act irrationally (Elster, 2007). However, this depends on the notion of rationality we have and on its status. There are five basic notions of rationality in the social sciences that can be classically linked to methodological individualism.

The first is to consider that individuals are rational whenever they act in an intentional way. The intentional decision to act corresponds to the reason someone has to act. An irrational behavior would then be to act on the basis of unintentional causes. For instance, Kahneman (2011) reports a study about parole judges observed in their decisions. Individual judges tended to be more severe when they were hungrier: clearly in this case unintentional and unconscious causes affect intentional decisions. This means that intentional motives do not have the sole influence in individual decisions; however, it is still individual decisions that are at stake, partly determined by unconscious trends.

The second notion of rationality is linked to the notion of consistency or transitivity of choices. The rationality is not related to the contents of individual choices as such, but to the fact that individuals are consistent in their preferences. This is the official position of neoclassical economics, where rationality does not involve any kind of 'right' decision but only the fact that people do not make incoherent decisions. Irrationality here would be to have inconsistent choices. But again, irrationality regarding consistency of choices would affect individual behaviors and thereby would be compatible with methodological individualism.

The third notion of rationality links it to an instrumental dimension of action, where an actor chooses the adequate means to reach an end. The rationality derives from an ability to select the correct means, which requires that a normative notion of correctness be implied. It should be noted that although instrumental rationality is widely associated with standard economics, it can be separated from it from two opposed points of view: first, as was noted by Weber, instrumental action does not necessarily imply any kind of economic motives. Second, the transitivity of preferences, which is the core of neoclassical theorization of economic action, does not in fact involve a notion of instrumental action.

The fourth notion of rationality is clearly the most widespread in the social sciences, although it suffers major ambiguities (Demeulenaere, 1996) and can be the subject of deep criticism. It is the idea that people act rationally whenever they efficiently pursue their self-interest (Coleman, 1990). This is a much narrower conception of rationality, which does not insist only on the means but on the ends of action: self-interest. In this scenario there is, however, a hesitation between two alternatives: either the preferences are supposed to be the same (like a preference for an increase of wealth) or they can be dissimilar (like smokers' and nonsmokers' preferences). This theory is strongly normative, because it reduces rationality to self-interest: this can be refuted from a philosophical point of view. However, here again, if it appears that actors are not rational in this sense – that is, if they do not behave out of strictly selfish motivations – this does not imply that it is not individual actions that are under consideration.

The fifth notion of rationality is much rarer in the social sciences, as a consequence of the influence of positivism: it extends its scope to the determination of right choices that can include not only correct beliefs but also normative deliberations. Boudon (2011) has advocated the reintroduction in sociology of this classical meaning of rationality in philosophy.

In sum, whatever notion of rationality is selected, an irrational behavior is by definition possible (otherwise it would be pointless to determine the conditions of a rational action); but there is no reason to consider that irrational actions are not individual actions, or at least individual behaviors. Therefore, rational behavior is not consubstantial to MI, even if there are reasons to consider that a rational interpretation of behavior should have priority over an irrational one, for one main reason, clearly expressed by Weber: when a rational behavior is possible, it can be expected that an individual will adopt it, because it is part of the normative idea of rationality that someone should adopt the correct rational behavior, when it is available. For instance, one should think that two and two make four, and not five. Therefore, if one adopts an irrational behavior, we need a further investigation to understand why it is the case. Naturally, from a more general point of view, we need a theory to explain why the human species is endowed with such a notion of rationality, with its normative pressure, and what are its contents and properties. We need to explain rationality, as much as we need to explain irrationality at a meta-level. But, for social science explanations, on the basis of a given theory of rationality (whatever the origins of rationality), a reference to rational behavior does not raise

supplementary questions, whereas the evidence of an irrational behavior raises the question of why the rational choice was not selected, when available. This is not intentional fundamentalism (Ylikoski, 2012) but a consequence of the normative dimension of rationality.

The Role of Situation and Institutions

From its beginnings MI has been attacked with the charge of 'atomism,' by Durkheim for one, on the ground that in this scientific tradition not only individuals do not interact but they are completely free of any social determination or influence. This critique cannot be accepted for two reasons. First, all major MI sociologists, as well as philosophers like Popper (1966) or Watkins (1957), have accepted the importance of social situations as necessary to the interpretation of individual behaviors. This is the case, for example, of Homans (1967). Thus when Wippler (1978) coined the term 'structural individualism,' to stress the role of social situations in individual behavior, it was largely accepted, for instance, by Boudon and Bourricaud (1990). The important thing is not to deny such an influence, but to understand the way it is exerted on actors, which occurs by various and heterogeneous ways. Therefore, it is not correct to describe MI as a refusal of the role of social situations on individual behavior, as Lars Udéhn (2001) describes it. Second, the alternative is not between socialized actors unilaterally depending on social structures, and nonsocialized individuals deprived of any kind of interpersonal relations and independent of any social influence. This is an untenable caricature. In the tradition of MI, people belong to social situations that exert influence on them: this is clearly the case for instance in Coleman's famous theorization of social action (Coleman's boat), where individual actions are understood only on the basis of their social environment.

However, four things must be added in this respect:

- In the tradition of MI, social factors exert an influence on individual actors, but individual actors are the ones who make the decisions, limited and constrained by these social influences. This means that social factors do not act by themselves, but individuals respond to and are constrained by social factors. It is, therefore, important to clarify and explicate the way in which social factors play a role in individual decisions.
- This means that we need to interpret social dimensions on the basis of nonsocial dimensions of individual behaviors.
- There is always a certain room for decisions, even in very constrained situations. It can be the case, however, that there is some kind of 'internalization' of norms or habits: this idea is accepted, for example, by Coleman (1990). It implies specific mechanisms that bridge social settings and individual behavior through psychological (and neuronal) adaptations, which are not necessarily clear and well understood. For example, people raised in a specific language tend to have the accent of this language when they speak another one.
- However, a specific feature of MI is to try to interpret the emergence of social institutions and social situations on the basis of prior decisions and individual moves. For example, the design of a specific keyboard (of the QWERTY type) makes all people constrained by the way it is to be used, although another layout could be more efficient. But we also know the reasons for which such a design was selected for specific purposes.

Infra-Individual Determination

The idea that only individuals act has been deployed by methodological individualists against holists or structuralists who evoked the action of social wholes. Today, it would be reaffirmed against theorists who claim the existence of a social causation that does not involve individual actors (Kincaid, 1996). MI has been challenged in return, more recently, by theorists who stress the importance of infra-individual determination of behavior, either at a psychological level or at a neurophysical level (Sperber, 2011). They underscore the existence of unconscious motives, and interpret their role as the necessity to go to a deeper level of determination of action, which is therefore termed 'infra-individual.' Consequently, there are social phenomena, based on unconscious motives, such as the diffusion of beliefs, that do not depend on individual deliberations.

There are two different things involved in this argumentation. First, as has been already said, there is no reason that MI should refuse the existence of unconscious motives that partly determine individual behavior (which is therefore partly intentional, partly unintentional). To acknowledge their existence does not lead to a refusal of the basic idea that only individuals act, even if this raises the complex problem of the relations between the conscious and intentional dimensions of behavior on one side and the unconscious and unintentional ones on the other. Therefore, whenever diffusion phenomena exist that do not depend on conscious choices, this does not mean that it is not through the means of active individuals (with their psychological characteristics) that those phenomena intervene. It would be meaningless to refer to beliefs without referring to individuals who support these beliefs and whose psychological mechanisms are responsible for their diffusion.

Secondly, unconscious motives and subintentional determination of behaviors are frequently associated with an 'inferior' level, which should be taken as responsible for actions, preferably at the individual level. But this is a misleading argument. It would rest on the idea that the inferior level has no role in the determination of intentional behaviors themselves. But there is no basis for this. If one accepts (as promoters of a subintentional determination of action do) that unconscious behaviors are determined by psychological or physical mechanisms that lie beyond the scope of individual awareness, it can be said – and it is in fact necessary to say – that conscious individual decisions and deliberations also rest on such subintentional mechanisms (that determine the strength of rationality). They are equally concerned by the mind–body problem. Therefore, a reference to psychological or unconscious motives does not straightforwardly lead to a subintentional level, because rationality itself necessarily rests on psychological and physical determinants. The infra-individual

level concerns rationality as well as irrationality: but to discover the biological mechanisms that are involved whenever a behavior is engaged, rational or irrational, conscious or unconscious, is not the task of the social sciences as such.

The Micro/Macro Transition and the Ontological Issues

So far, following Weber, I have described MI as a theory asserting that, in social life, only individuals act. This is not an ontological position about the existence of individuals or of social facts. However, it poses the problem of the relation between individuals and social entities, classically named the 'micro/macro transition' (Little, 1998). It involves the determination of what the social entities are and the nature of their link to individuals, that is, the issue of so-called 'levels' in the geography of social life. Those problems are related to ontological questions about what is considered to exist in social life.

When we refer to the micro/macro relation, two positions are possible. One is very general, and will consider that the micro-elements are the parts of any set that includes them. For instance, administrative entities are usually hierarchically dependent on other superior-level administrative entities (cities, regions, states, supranational organizations). Each level can be named and treated as a quasi-actor: it can be said, for example, that Russia and the United States are players on the global scene. Therefore, micro and macro entities do not refer to specific levels, but to positional relations: for any macro level, there is a micro level.

However, two caveats should be added to this first position. First, because Russia and the United States, for example, are stable, long-term existent countries, they clearly have properties that are stable beyond individual decisions. For instance, they have a size that does not depend on actual individual decisions (and that exerts constant constraints on the succession of people who are in charge of these countries). However, even if it is not meaningless to speak of a Russian or an American strategy, in the long run, beyond actual individual decisions, due to the existence of those lasting properties, in fact any interpretation of actual decisions by one of the states necessarily involves singular individuals (presidents, ministers, and so on). Quasi-actors are not actors in the same way that individuals are. Quasi-actors need singular individuals to be active, so that there is a privileged level in order to achieve sound interpretations of the behavior of quasi-actors.

Second, it would not be correct to describe a relation of 'emergence' between the various levels: states are not emergent regarding cities, although it can be said, from an administrative point of view, that cities belong to a state and are parts of it. Moreover, the same elements can be part of various social sets that do not overlap. For instance, an individual can be the member of a football club, and the club can be part of a league in which countries as such play no role. The football player can be also the member of a club that belongs to a country that is not his own. There is no such thing in social life as a unique hierarchy of levels where superior levels emerge from inferior ones. Therefore, the analogy with the infra-individual level and the individual level is clearly misleading: it is not at all the same type of relation, because it cannot be said that the social emerges from the individual in the same sense (however problematic it is) as the mind would emerge from its body determinants.

This is why, although it is possible to conceive the micro/macro relation as a purely positional relation, where no specific level is privileged, and where institutions can be treated as quasi-actors, it is still important for MI to reaffirm that quasi-actors necessarily depend on singular actors to be active. And this is the second and more important meaning of the micro/macro relation: macro-level institutions, organizations, or rules are necessarily referred to singular actors (embedded in social situations) to be understood.

What are then the social facts? There are many words that are commonly used, particularly 'collective,' 'structural,' and 'system' level. The whole/part is equally associated with this micro/macro relation. All of this is relatively imprecise and refers to various realities that pose different ontological problems.

I would suggest (Demeulenaere, 2011) that there are basically three types of social facts regarding an individual level.

First is the distributional properties of an aggregate, such as a mean. For example, we can select at random the people who enter a shop and determine their average age. In this case, it can be said that there is a whole, because we select a definite number of persons, but there is certainly no such thing as an emergent whole regarding the parts. The constructed measure of the mean does not correspond to the properties of a whole as such, in the same sense as the age of one person is a property of this person (although this property is by no way a physical property, because it involves various institutional considerations about the appropriate way of measuring the age). The notion of aggregation can be here misleading. If we add up a series of stones, we have an aggregate, which has specific properties (for instance, it might have a pyramidal shape). The aggregate has emergent properties (height, length, and so on) that the individual stones do not have. As opposed to this, when we measure the average size of the stones, we do not refer to this whole as such but to the individual stones taken together. So the aggregate in this case can correspond to two different things.

A second meaning of the macro dimension corresponds to the relative positions of a series of elements: for example, one individual is taller than another, or richer, or more powerful. Here again, it could be possible to speak of a whole, or of a level, but these are metaphors that have no substantial basis: there is no emergence of a specific whole or of a level beyond the set of elements that are envisaged from the point of view of their relative positions.

Finally, common rules that are followed (or rejected) by individuals represent a macro dimension regarding elements involved. These rules can include norms and institutions. Sometimes norms and institutions give birth to quasi-actors, which is not the case in the two previous cases. In this case, it is easier to speak of a group level, because people can have a sense of belonging to the whole. This is why Searle's social ontology has focused mainly on this type of situation. However, the notion of a 'superior' level is ambiguous here, because rules, norms, institutions, and organizations depend

on actors for their life. They can be said to emerge as a social novelty, but they can disappear if nobody follows them.

All of those dimensions pose various ontological problems, which will not be discussed here. The idea that only individuals act has no direct implication regarding the ontology of social facts, because they are clearly existent things that do not act. The main position of MI is one about the fact that only individuals act, not about the existence of social facts. The ontological problems depend on the notion of what an existent being is, and various positions will be possible regarding this. An organization can be said to exist even if it does not have the physical properties of an individual. A measure exists, even if the mean to which it refers does not exist from a physical point of view. The debate is not so much about whether social facts exist or not (it would be absurd to consider, for example, that the United States does not exist) but what type of social facts exist, and what is their mode of existence.

Explanation

The main proposition of MI concerning the fact that only individuals act has consequences for the relevant explanatory strategy in the social sciences. Globally, it is said that social facts should be explained by reference to individuals who set in motion social life. In particular, correlations between social variables (for instance, gender and academic success) have to be explained by individual actions and decisions in a given context (Boudon, 1974).

But the actual requirements for relevant explanations depend on the nature of the social facts considered and of their relation to individuals. The relation that exists between a series of individuals and a collective measure is not the one that exists between a set of individuals and the norms they adopt or refuse. In the first case there is no social novelty to be explained, and the collective measure logically derives from the individual measures. In the second, opposite case, norms represent a social novelty regarding individuals, and are to be explained genetically by their beliefs and decisions in a given situation.

The consequence of this is that although the requirement of MI is to insist on individual actions, because they are embedded in a social context that plays a role in their decisions, we cannot say that the macro level is explained by a micro level: since a specific social context is necessary to interpret the individual decisions, one dimension of the macro level is necessarily involved in the explanation of another dimension. However, a given context, locally admitted for the purposes of a definite explanation, can be, from another point of view, the focus of explanatory efforts.

Therefore, two positions should be rejected: one that would say that MI requires referring only to a micro level in order to explain macro-level phenomena, because any explanation actually involves macro dimensions. And second, it would be incorrect to accuse MI of intentional fundamentalism, because any explanation involves a reference to social settings and can include unconscious dimensions of behavior.

Methodological Issues in the Study of Sexuality

Stuart Michaels, Academic Research Centers, NORC at the University of Chicago, Chicago, IL, USA

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Social scientific research on sexuality has grown enormously in recent decades primarily driven by demographic and health concerns. Focusing on the problems of sample-based surveys, the methodological challenges related to sampling (generalizability) and interviewing (measurement error) are discussed. The design of sex research must begin with the clear conceptualization and operationalization of sexuality. Gaining participation by selected participants and minimizing bias and error in response through the formulation of questions and maximizing privacy of response are emphasized.

Introduction

Social scientific research on sexuality including surveys has experienced an enormous increase in recent decades. Many factors have contributed to this increase, among them the 'sexual revolution' of the 1960s, the social movements such as Feminism and what is now called the LGBT (lesbian, gay, bisexual, and transgender) movement, as well as the HIV/AIDS epidemic. The social and historical context affects all scientific research shaping and motivating research questions that address pressing social concerns and problems. This is especially true in the area of sexuality where legitimating research is especially important to overcome interpersonal, moral, and political reticence and taboos about asking and answering questions that touch on the private and personal (Ericksen, 2001).

Definition of Sexuality as the Object of Research

While our main concern is methodological, that is how our research decisions and practices affect the generalizability and validity of research findings, we first need to address the definition of sexuality as an object of research. Sexuality as a coherent, analytically distinguishable object of scientific research dates to the second half of the nineteenth century. Sexuality emerged as a modern topic and a discipline with reference to biology and medicine in their association with psychiatry and psychology, with its origins closely tied to criminal justice and debates about whether 'psychopathia sexualis' (sexual psychopathology) should be treated as crimes or mental illness (Krafft-Ebing, 1906/1929; Bullough, 1994). The scientific study of sexuality emerged at the nexus of the medical or biological and the social. In order for sexuality to emerge as an object of scientific interest, to give rise to a scientific discipline of its own, sexology, and to attract the interest of researchers, it had to be distinguished from procreation and reproduction (Katz, 2007). The initial focus was on pathology, on psychopathologies and perversions. It is interesting to note that of the terms that organize much of contemporary research and debate, homosexuality was coined before heterosexuality. In this context, sexuality is conceived of in terms of desires and drives used to explain problematic behaviors.

Sexuality is a broad and complex topic that has been studied using a variety of methodological approaches: from case studies, to laboratory studies of sexual response, ethnographic fieldwork, to population surveys. Each of these approaches poses their own special set of methodological issues and expertise. This article focuses on one of the main approaches to the study of sexuality in the social sciences, the population survey. The methodological issues in population surveys apply to the other approaches mentioned earlier as they invariably involve forms of interviewing and self-report on sexuality. The formative paradigm for population surveys on sexuality developed out of the work of Alfred Kinsey and his colleagues, which began in 1938 in the United States (Kinsey et al., 1948, 1953; Robinson, 1989). While Kinsey's work has been criticized for not using probability sampling, its aim was to represent the variation in sexuality in a defined population from which respondents were drawn via interviews that would elicit honest answers to the questions posed (Cochran et al., 1953). The two aims, representative sampling and valid measurement, will serve to organize this discussion of the main methodological issues in the study of sexuality. However, there is one other issue which should be discussed first, the definition of sexuality in research.

In the movement from theory to specific research questions, too often insufficient attention is paid to the choice of what, specifically, is to be studied. Research is always a series of choices and these choices affect what we can learn. They also affect the answers we get. In the context of any research that depends on interviews, the choices of what questions to ask and how to formulate them are critical. Alfred Kinsey and his colleagues' work is instructive (Kinsey et al., 1948; Gathorne-Hardy, 2000). Kinsey was a zoologist and after having studied the gall wasp, he turned his attention to sex in humans. Kinsey's focus was on 'sexual behavior,' and his goal was to describe the variation in this specific aspect of sexuality across the population which he defined as 'humans' specifically 'males' and 'females.' The decision to focus on behavior is a fundamental conceptual leap that has been enormously influential on subsequent research on sexuality, but this must still be operationalized in any given study (Michaels and Giami, 1999). What defines a specific behavior or act as sexual? Kinsey's approach was to use the 'orgasm' as the characteristic that defined a behavior as sexual. This had much to recommend it, but it is not without problems. It had the great

advantage of being clear and quantifiable. It allowed Kinsey to achieve a degree of objectivity and aided in quantitatively equating a broad array of behavior from wet dreams to masturbation, from noncoital events (in Kinsey's now dated term, 'petting'), as well as homosexual and heterosexual experiences. He focused on the concept of 'outlet,' asking questions such as what proportion of the total outlet was accounted for by any particular form of activity. In retrospect, we can see that this choice has a masculine bias (Robinson, 1989). Men are more likely to view their sexual experiences and lives in terms of events that result in an orgasm, but this is much less the case for women. Kinsey himself was aware of this problem when he began to analyze the data from women and had to add a whole discussion of the problem of orgasm and counting in his second volume, *Sexual Behavior in the Human Female* (Kinsey et al., 1953).

Definition of Sexuality in Surveys

Sexual behavior remains at the core of population surveys since Kinsey. Most of these surveys have been prompted by two main issues: fertility (cf National Survey of Family Growth) or public health concerns about sexually transmitted infections (STIs) especially HIV/AIDS (cf the National Health and Social Life Survey (NHSLS) in the U.S. (Laumann et al., 1994)), the NATSAL surveys in England (Johnson et al., 1994), and the ACSF survey in France (Spira et al., 1993). In these surveys, the focus has been on sexual partners and practices, especially practices associated with prevention either of pregnancy or STIs. All such surveys are confronted with how to define sex and what constitutes a sexual partner. In the NHSLS, we decided to use a relatively broad definition when eliciting an enumeration of partners in the past year. Here is how this was presented to respondents:

> Now I am going to be asking some questions about your sexual activity during the last 12 months. People mean different things by sex or sexual activity, but in answering these questions, we need everyone to use the same definition. Here, by 'sex' or 'sexual activity,' we mean any mutually voluntary activity with another person that involves genital contact and sexual excitement or arousal, that is, feeling really turned on, even if intercourse or orgasm did not occur.

> In answering these questions, please include all persons or times in the last 12 months where you had direct physical contact with the genitals (the sex organs) of someone else and sexual excitement or arousal occurred. Certain activities such as close dancing or kissing without genital contact should NOT be included. Also, this set of questions does NOT refer to occasions where force was used and activity was against someone's will.

Sex was defined as mutually voluntary activity involving arousal and physical contact with the genitals but not necessarily penetration or orgasm (Laumann et al., 1994). (Nonvoluntary sexual experiences were asked about separately in a later part of the interview both to minimize emotional distress and because it was not considered in the basis for defining sexual partners.) The goal was to avoid a normative definition of sex as heterosexual, involving vaginal intercourse, and to provide a clear definition that would be equally applicable to women and men. In addition, in the context of a survey motivated by concerns about HIV/AIDS, every effort was made to have a definition that would elicit reporting of both male and female partners for both men and women.

Measurement or Response Error in Surveys

One of the greatest concerns when asking about sexuality in interviews is whether subjects will answer truthfully. Asking about sex in surveys is a classic example of a 'sensitive question' that is a likely source of bias or error in reporting. Sensitive questions are those that produce the largest item nonresponse rates and are most subject to social desirability effects (responses skewed in the direction of social norms). Sexual behavior is a classic example, along with drug use, abortion, voting, and income. Income questions generally have the highest item nonresponse of any survey questions. Social desirability effects on illegal and/or highly disapproved behaviors produce underreporting. Behaviors that are desirable such as voting or having a library card are overreported. There is a fairly extensive survey research methodology literature on these questions (see Tourangeau and Van (2007) for a recent thoughtful and thorough review of this literature). There is also a literature on measurement error specifically applied to sex surveys that has mainly developed as HIV/AIDS motivated attempts to improve the methods of improving data on risk behavior, for example Catania et al. (1993) and Fenton et al. (2001).

From a methodological perspective, the goal is to minimize this form of error even if it is not possible to eliminate it. It is a goal in all surveys and many of the standard practices in surveys are intended to achieve this goal. First and foremost is the assurance of confidentiality of responses.

Researchers must make a convincing case for the legitimacy of the research, for example, that it serves an important public health goal. They must ensure participants that the confidentiality of their identity, their participation, and the information they provide is a central commitment of the research enterprise. This assurance is an important tool in convincing respondents that they can and should provide honest answers to the questions posed. It is essential to make every effort to communicate to respondents that they are not being singled out but that the research goal is to understand the ensemble of persons interviewed. As part of informed consent and protection of human subjects, respondents are always informed prior to making a decision to participate in a study that they do not have to answer any question they prefer not to answer.

The role of the interviewer is that of a 'professional stranger' who the research subject will not see again and is just doing a job. This is in fact a great advantage of survey research interviewers over other professionals who might be called upon to ask questions about sexuality such as physical or mental health professionals. The latter are asking the questions as part of a treatment protocol and are likely to have some ongoing contact with the patient. Instilling an attitude of neutral sympathetic interest is part of the standard training of interviewers and is especially important in the area of sex research.

This involves a combination of desensitization to the subject matter at hand to minimize any reaction of surprise or judgment in response to answers to questions and a general sympathetic and encouraging affect toward the respondents' efforts to answer honestly. At the same time, interviewers are trained to not express too much interest and to remain neutral in their attitudes toward whatever is reported.

In spite of the many advantages of personal interviewing whether face to face or by telephone – the ability to insure that questions are asked as written and the responses given correspond to the categories intended and are recorded accurately as well as the ability to respond to and detect any misunderstanding of the questions on the part of the respondent – a great deal of research has shown that response effects are strongest when answers are produced verbally to an interviewer (Tourangeau and Van, 2007). While there is no way to eliminate these problems, there are techniques to reduce their impact. It has long been known that self-administered questionnaires where answers are not shown or known to the interviewer produce higher rates of reporting of sensitive questions. One technique used in face-to-face interviews before the widespread use of computers by interviewers was to have respondents answer especially sensitive questions on a self-administered form and put these forms in a sealed envelope. This depended on the respondents having adequate reading and writing skills. With the expansion of the use of computer-aided interviewing, Audio-Computer Assisted Self-Interviewing (ACASI) was developed (Couper et al., 2003). Used in face-to-face interviews, the respondent is given the computer which has questions and responses on the screen and an audio track that reads the question aloud. Respondents still need a minimal level of literacy to be able to select response categories (e.g., recognizing numbers or letters) and a degree of familiarity and comfort with computers. This technique tends to produce the highest reporting of socially undesirable behaviors, including sexual behaviors, and to reduce social desirability biases such as the tendency for men to report higher numbers of sexual partners than women. Another advantage of ACASI over the older form of self-administered paper and pencil forms is that computerized forms can incorporate and guide respondents through more complex skip patterns. A similar technique to ACASI has been developed for telephone surveys, interactive voice response. The sensitive questions are administered by a recording rather than a live interviewer and the respondents provide their responses via the telephone keypad or by saying aloud the number corresponding to their answer. While ACASI represents an effective technique to reduce response error due to social desirability, it is cumbersome and may not be feasible in some research settings. It also does not eliminate the need for careful attention to other issues in questionnaire design.

The design of questionnaires and the application of established principles of question construction and survey design remain essential. In this area as well, there is an extensive literature and accumulated experience (Schaeffer, 2000; Schwarz, 1999; Sudman and Bradburn, 1982; Sudman et al., 1996). The details and precepts of this literature are far beyond the scope of this discussion. A couple of points can be made. First, it should be borne in mind that answering questions about sex involves the same problems and processes as answering any questions about behavior: comprehension of the question, recall, and formulating a response. The clarity of the question and the minimization of cognitive burden in searching and processing the necessary information to formulate an answer are as important to questions about sexual behavior as they are any other activity. Once engaged in an interview, respondents follow similar conventions of usual conversational exchange and these include trying to provide honest and useful information. Many of the well-known context effects in survey design, e.g., question order effects, effects of rating scales, can be traced to respondents' attempts to use (often inadvertent) signals provided in questionnaires that lead them to infer the implicit expectations built into the questionnaire. For example, if the response categories for a question about numbers of partners in a given period of time imply low or high numbers, answers will tend to skew in the direction implied.

Language and Terminology

A major concern in interviewing about sex is the type of language and terminology to be used. The goal is clarity and comprehension of questions. Another goal is to be culturally sensitive and there may be a temptation to use slang and/or euphemism. This is to be avoided. The general principal, especially important in general population surveys, is to use simple, clear, and unambiguous language. Common terms are best that can be understood by the widest spectrum of respondents including those with the least education. The pilot testing of questions and, where feasible, the use of cognitive interviewing on a small but diverse sample that includes less educated respondents is desirable (Willis, 2005; Miller, 2011). This can help to find terms that are understandable such as 'having sex' as opposed to intercourse, 'sex organs' instead of genitals, 'butt or rectum' instead of anus.

Representative Sampling and Generalizability

Sampling is a central concern in all empirical social science research. With limited resources, we are almost never in a position to study the whole population of interest. So we study a sample to learn about the larger population from which our sample is drawn. A representative probability sample is the gold standard. It is the only method that allows one to derive estimates from a sample that can be generalized to a larger defined population and allow one to quantify the likelihood that the derived estimates approximate the true values in the population. Often in sexuality research, some form of non-probability, usually a purposive or convenience sample is used. To some extent, researchers justify this for one of the two reasons. Either the population of interest is too small or hard to reach via probability sampling, e.g., sexual minorities such as gay men or lesbians, or because the researcher does not believe that randomly selected subjects will participate. The latter was Kinsey's position. Ironically, Kinsey the pioneering and committed empiricist did not test this belief, but accepted it as

given and then proceeded to try to collect as diverse and large a sample as possible to insure that his findings were representative. While understandable in the era in which he was working (1938 to the early 1950s) before the widespread use of surveys and a fuller understanding of the use of probability sampling, it was not until much later that extensive questions about sexual behavior were asked of respondents drawn from a probability sample. With reasonable skill and care, these surveys have achieved response rates and high-quality samples comparable to those in surveys on other topics. Whenever affordable and possible, probability sampling should be used. Binson et al. (2007) provide an excellent overview of sampling issues related to surveys on sexuality and alternative approaches to true probability samples.

Heterosexuality

This discussion has not focused specifically on heterosexuality. First, the methodological issues discussed do not vary or depend on whether we are talking about heterosexuality or homosexuality or any other form of sexual behavior, practice, or affect. In addition, heterosexuality as a category is not as transparent as one might assume. Sexuality is similar to what at first glance appear to be fixed, unambiguous demographic categories such as sex and race; their reality is complex and therefore demands careful theoretical and methodological consideration when we attempt to measure them (Prewitt, 2013). It is most often the normative categories of male/female, whiteness, or heterosexuality that most easily escape conceptual and methodological scrutiny.

For many years, data on sexual behavior were collected in the context of concerns about marriage and reproduction. In that context, often studies confined themselves to studies of married persons. As interest has broadened to include sexuality, we need to consider how the design of research determines the research questions that can be addressed. Heterosexuality is not as easily distinguishable substantively and isolatable from other forms and moments in sexuality. Researchers should not presume a priori that heterosexuality is a fixed, clear category. Even if it were to turn out to be the case in general or for certain individuals or within a given time period, it is better to approach its study without building this into the research design or formulation of the questions to be asked a priori. The evolution of the National Survey of Family Growth is instructive (see the excellent NSFG website at http://www.cdc.gov/nchs/nsfg.htm). When the NSFG began in 1973, the sample was confined to women who were or had been married and unmarried women living with their own children between the ages of 15 and 44 and it only asked questions about heterosexual partners and sexual and contraceptive practices. In the third cycle of the NSFG (1982), it expanded its sample to both single and married women in that age range, and starting in 2002, it included men as well as an expanded range of questions about both same and other sex partners and practices. While complicating the notion of heterosexuality, this design allows a much more nuanced exploration of questions about who is heterosexual and what this means. In retrospect, it is clear that the latter design produces a much fuller basis to understand heterosexuality and heterosexual practices than the more restrictive earlier framework. While this larger frame may make it more difficult to operationally define 'heterosexual' as a substantive referring to persons, it allows one to ask a much richer range of questions and to gain a more profound understanding of heterosexuality.

As has been true throughout the history of sex research, the focus has often been on the more troubling and non-normative aspects of sexuality most often in response to a pressing social or health problem. These research efforts have led to methods and data that have broader applicability. Thus, much recent population research on sexuality has been motivated by concerns about HIV/AIDS and a concern about non-normative sexual practices and identity. As the LGBT communities have mobilized politically, they have generated increased scientific interest which has informed work on sexuality more generally (IOM, 2011). One case in point is the in-depth work that has been done to improve questions about sexual identity for large-scale national health surveys (Miller and Ryan, 2011; Ridolfo et al., 2012). In-depth qualitative work on question wording for a general sexual identity question has shown that the inclusion of 'heterosexual' in this question creates the largest amount of nonresponse and mistaken responses. While persons who are members of a sexual minority, e.g., LGBT persons, understand this term, less educated respondents have trouble understanding terms such as especially 'heterosexual,' but also 'homosexual' and 'bisexual.' Sexual identity is a less salient aspect of the lives of the large majority of the population who are not constantly confronted with reflection on their status. Many think of themselves as just 'normal' and yet in most research contexts we would want to classify them as heterosexual. For those who have trouble answering an identity question, or who refuse to answer the question or respond with 'don't know,' the explicit term heterosexual is confusing.

Conclusion

This discussion has focused on the methodological issues in the design of population surveys on sexual behavior and the major threats to generalizability and measurement error. The principles discussed apply to other forms of research on sexuality such as qualitative interviews or research focused on psychological states (desire, attraction, or fantasy) or the meaning associated with sexuality. The methods used need to be in service to the research questions and objectives. The methods and principles discussed here derive from quantitative research such as demography or epidemiology that has as its primary goal the quantitative description of a population. Qualitative research often has other goals such as understanding the complexity of meaning and sense-making processes that may be individual or cultural. But the same issues of generalizability and validity of measurement apply and the lessons and advances in the area of surveys are still instructive.

The methodological challenges in research on sexuality are no different than those faced in any other type of empirical social scientific research. This may be the most important precept to remember. In spite of the aura of taboo and special significance that we often associate with sexuality, we would do best to assume the opposite (Rubin, 1984). Rather than

assuming that research subjects will not be willing to report on their sexual feelings and behaviors and thereby practice a form of scientific self-censorship, we can make the greatest contributions to knowledge by taking the position that sexuality is an important part of social life and that needs to be studied with the same methods and rigor as any other. This has been demonstrated over and over again, especially since the 1990s. When presented in a sober and serious manner, with a clear statement of the scientific and social usefulness of the inquiry and the same assurances of confidentiality of responses as in any enquiry with human subjects, members of the general public have shown their willingness to answer questions that touch on what is generally considered their most private acts and feelings and to participate in research on sexuality at the same rates as in any other type of survey. The study of sexuality is subject to the same limits and errors of measurement as all empirical scientific research and the same promise of cumulative advance of knowledge.

Methodology of the History of the Social and Behavioral Sciences

Christian Fleck and Christian Dayé, University of Graz, Graz, Austria

© 2015 Elsevier Ltd. All rights reserved.

Abstract

The history of the social and behavioral sciences (SBS) gets varying coverage in different disciplines. Regardless of these differences, we sketch a general and descriptive methodology for the historiography of SBS. The approach is not to seek for a consistent reconstruction of how to correctly write history, but to observe historians of SBS at work empirically. This, at best, results in a collection of models of best practice that can guide future research on the history of SBS. In all brevity, we do this for five units of analysis: (1) Actors; (2) Ideas; (3) Instruments; (4) Institutions; and (5) Contexts.

The past of the social and behavioral sciences (SBS), their 'history,' gets varying coverage in different disciplines. While the natural sciences are well covered within the 'history of science' field, this is not the case for the SBS. A comparable overarching specialty 'history of SBS' does not exist, and the various SBS disciplines handle the problematic of their past differently. In some disciplines we find specialized journals, research groups, and doctoral programs, whereas in other disciplines some or even all of these specializations are lacking. The intensity with which the trajectories of the disciplines are researched varies strongly.

Regardless of these differences, in this article we venture to draw a portrait of one aspect of the historiography of SBS, its methodology. We start by describing several analytic perspectives that histories of SBS can take and subsequently develop briefly what might be called an empirical methodology of history in the SBS.

Analytic Perspectives

The history of a particular discipline consists of narratives about former periods and the trajectory of the discipline. Different approaches to writing such a history have evolved over time. A 'philosophy of science' perspective strives to reconstruct the logical structure of the system of propositions, their relationship to underlying assumptions, and to particular statements. The aim is to advance scholarship by distinguishing good science from bad science, truth from error. A 'history of science' perspective is less concerned with the logical preconditions of science but with the detailed reconstruction of particular cases of scientific research, theorizing, controversy, and debate. The *sociological perspective* on the history of science and scholarship analyzes the opportunity structures enabling scholars to fulfill their professional obligations by emphasizing the role of norms; the modes of assigning prestige and recognition to scientists; the influence of historically contingent institutional arrangements; the forms of collaboration; and the prevailing convictions, cultural moods, and world views held by scientists. Sociologists of science are not concerned with history per se but make use of past cases and arrangements, partly because it is easier to show a detached stance toward bygone situations, but also because present-day practices are less observable than 'closed cases,' and finally because sometimes past affairs are better documented and archives more easily accessible. More often than not practitioners from these three branches got their original training in different fields of scholarship. As a consequence, the exchange of ideas, the communication across disciplinary boundaries, and therefore the mutual enrichment have been diminishing over the last decades. These fields – philosophy of science, history of science, and sociology of science – became increasingly exclusive areas, i.e., specialties in a narrow sense, and tended to look inside rather than to neighboring discourses.

A further peculiarity stems from the fact that analyzing science requires some familiarity with the subject itself; in the early days of the philosophy of science movement, its exponents claimed that one needs to have training in the particular discipline one studies in order to carry out such endeavor with success. When the 'history of science' field began to blossom in the early twentieth century, the requirements have been even more far-reaching; students were expected to be universally educated cosmopolitans mastering several languages and disciplines, and to command a good knowledge of with the history of thought from the early periods on (George Sarton functioning as a role model). Only when the second generation of sociologists of science entered the stage, the attitude toward the subject under investigation changed considerably. Adopting the habitus of anthropologists, these scholars left the historical approach behind and went into the field like ethnographers. Members of (scholarly) tribes were asked to make their laboratories available to participant observers who then recruited 'local' informants to explain what they were doing when they professed to study, e.g., the nature. Alleged ignorance functioned as a device to identify the assumptions underlying the practices of science. Detailed historical knowledge, or even awareness of the field's past, was deemed to undermine the methodical alienation that is a prerequisite for any good ethnography. When this mind-set had been established successfully within academic discourse, devotees of social studies of science applied their novel conceptual schemes to past stages of scientific research too. As a side effect, these mostly constructivist scholars got rebuttals from ontological realists. The 'science wars' of the 1990s left behind what warfare usually does: burned grounds, with both parties claiming ultimate victory.

The portrait would not be complete without mentioning a fourth type of history of science authors: Scholars writing the history of their own discipline. At best their contributions show

a discipline's degree of reflexivity; at worst they worship the successes of their authors' teachers. Usually such *historians of their own discipline* lack any training in history and do not look at their case from a comparative point of view; nonetheless, they sometimes deliver rich source material for further studies. In most cases, their audiences are discipline-compatriots, and references to philosophy/history/sociology of science literature are weak or even inexistent. Very often this type of historical analysis follows the lines of reconstructing the development of particular theories and covers the past primarily as a huge reservoir of ideas.

Today, history of science and philosophy of science, besides regular calls to collaborate more closely, are relatively separate communities with distinct patterns of scholarly communication. Specialized journals mark the boundaries of the discourses. Few departments and graduate programs unite both fields – however, SBS are very rare research topics in history of science departments. History of science primarily deals with the history of natural science; the same holds true for the interdisciplinary field of science studies. The whole field of sociological investigations has been split apart, and the only remaining shared denominator is the preference not to analyze their own disciplinary field and its trajectories over time.

Some aspects of the history of SBS, ideas, and theories in particular, are part of standard university curricula in some disciplines, but this has not led to a consolidation of the history of SBS as an autonomous field of research. Organizations devoted to the history of particular SBS disciplines are rare, one notable exception being the History of Economics Society (founded in 1974), whereas several associations are concerned with the history of a multitude of disciplines (e.g., Cheiron: The International Society for the History of the Behavioral & Social Sciences, founded in 1968; the European Society for the History of the Human Sciences, founded in 1982). Major international SBS associations have, if ever, only reluctantly introduced adequate sections or research committees. For instance, the American Anthropological Association (AAA) has no section on the history of the discipline (cf http://www.aaanet.org/sections/, accessed September 2012). The same applies for the European Association of Social Anthropology and the European Sociological Association. Compared to the other sections, American Sociological Association's History of Sociology section is relatively small. The Research Committee History of Sociology of the International Sociological Association is kind of an exception: It is relatively old and prospering. There is also a scarcity of specialized journals, with the *Journal of the History of Economic Thought*, the *Journal of the History of the Behavioral Sciences*, *History of the Human Sciences* and a few others as exceptions.

An Empirical Methodology

There are countless alternative understandings of the very notion of methodology extant in SBS literature, but most fruitful in our context seems to be an understanding inspired by the Paul F. Lazarsfeld's dictum that while a sociologist studies man in society, the task of the methodologist is to study the sociologist at work (Lazarsfeld, 1982: 171). Our task, thus, is not to seek for a logical and consistent reconstruction of instructions for how to correctly write the history of SBS, but to observe how historians of SBS do their craft. This, at best, results in a collection of models of best practice that can guide future research on the history of SBS.

In principle, historiography in the SBS is concerned with five kinds of units of analysis:

1. Actors: The history of individual scholars, of groups of like-minded authors, of generations and cohorts
2. Ideas: The history of concepts, theories, and research programs
3. Instruments: The history of methodologies, methods, techniques, and research practices
4. Institutions: The history of institutions and organizations
5. Contexts: The history of the embeddedness of science in larger social, political, cultural, and economic environments.

Actors

Traditionally studies of the history of SBS focus either on actors or ideas. Looking at actors as the unit of analysis, it can be observed that the most prominent level of aggregation is the individual. The vast majority of publications in the history of SBS are engaged in one way or another with individual scholars. Practically all leading figures from all SBS disciplines received coverage of their life and work in longer or shorter biographies (and the present Encyclopedia follows the path of its predecessors by including biographical articles on leading individuals). The standard mold of intellectual biography, life, work, and influence, claims much of the space, besides regularly raised reservations about obvious shortcomings (Gross, 2008). Collins argues persuasively that even genius-like authors happen to develop their ideas in chains of interaction with others (Collins, 1998) but his elaborated methodology found only very few follow-ups (Savelsberg and Flood, 2011). Missing in Collins' argumentation is, however, the role of the private life of scholars, which has rarely been studied systematically but is covered widely in all types of autobiographical writing. Some books contain chapters on teacher–student relations, collaboration with like-minded contemporaries, and debates with competitors (Merton and Riley, 1980). Another branch of this literature is concerned with particular research groups, schools, departments, universities, etc. (e.g., Bulmer, 1984a; Dahrendorf, 1995; Farrell, 2001; Wheatland, 2009). At an even higher level of aggregation, we have prosopographies, collective biographies, and investigations making use of the concept of generation (Blaug and Vane, 2003; Fleck, 2011). Rather popular are reports on the development of disciplines in particular nation-states (Halsey, 2004; Calhoun, 2007).

Mostly lacking are investigations on structured career patterns and the demographics of disciplines, glimpses of which can be found in the *World Social Science Report* (UNESCO, 2010; Mills et al., 2006). Sociologists focusing on actors seldom transgress Rankean narrative history by employing conceptual schemes form their own discipline. Merton's paradigm for sociology of knowledge (Merton, 1996: 208) did not attract many followers whereas in recent years,

Bourdieu's field theory and his distinction between different modes of capital entered center (Bourdieu, 1988).

Ideas

The reconstruction of the succession of leading ideas revolves around central concepts, theories, etc., mostly in the manner of the history of ideas approach in philosophy and human sciences (Grafton, 2006). At the core of a history of ideas approach stands the vision that ideas beget ideas, either by differentiation or by refinement. Whereas professional historians of ideas tend to analyze single entities or unit-ideas (Nisbet (1970) following Lovejoy (1936)), historians of SBS prefer compositions of ideas, or 'theories,' as their unit of analysis (Parsons et al., 1961; Coser, 1971; Weiler, 2014; Isaac, 2012). In the beginning, the succession of systems of propositions, their configuration and reconfiguration, has been seen as following a path of progress; later stages were seen as improvements compared to older versions, and the overall perspective remained more or less linear: later theorists were able to see further because of their standing on the 'shoulders of giants' (Merton, 1993). Since the middle of the 20th century, however, historians of SBS ideas tend to restrict their attention to particular outstanding individuals, either in the way of writing intellectual biographies of single authors or analyzing small groups of closely connected individuals, often under the label of schools (Schumpeter, 1954; Bottomore and Nisbet, 1978).

One can further differentiate the ideas according to their 'epistemic' status. Ideas, in their broadest possible meaning, can be ranked according to the degree of their explicitness. The history of ideas approach offers a variety of concepts: The 'zeitgeist' is one well-known candidate, 'tacit knowledge' (Polanyi, 1966) another one, and Ludwik Fleck's 'style of thought,' a third one (Fleck, 1979). All three share the characteristic that members of later cohorts are able to identify those thoughts easily, whereas even the most outstanding coevals had troubles to transcend them.

More explicit are sets of ideas that have been assembled into research programs. Such programmatic announcements are by their very nature explicit, and usually appear in plural. Lakatos was the first who elaborated the concept of research program (Lakatos and Musgrave, 1970). This concept has for instance been applied to economics (Marchi and Blaug, 1991; Boumans, 2012). At the core of a research program is a set of propositions which are of crucial relevance for the whole program and which is therefore defended against attempts to prove them wrong. In this area, there is considerable overlap with SBS theorists striving to reconstruct past research programs, but their neglect for the social conditions of the original formulation of the program as well as some SBS historians' exaggerated claim to explain all aspects of a research program by social factors renders collaboration difficult.

Several attempts at conceptual and theoretical innovations have been ventured recently: A dialogical turn (Levine, 1995; Camic and Joas, 2004) or a new sociology of ideas (Camic and Gross, 2001; Camic, 2010) were proposed. Outstanding studies by social science giants as Albert O. Hirschman (1991) and Robert K. Merton (Merton and Barber, 2004), who traced the rhetoric of reaction and the emergence of the concept of serendipities, respectively, did not find followers so far but offer a distinct perspective on the trajectory of bundles of ideas (Zuckerman, 2010, 2011).

Instruments

A much less frequently covered aspect of SBS's historical development concerns 'instruments.' In the hard sciences, the very notion of instruments refers to clear-cut real things, such as air pumps, microscopes, and petri dishes in the early days, and highly complex and costly things in recent times, such as satellites orbiting our planet, medical imaging from X-ray radiation to DNA sequencing, not to mention colossal machineries like CERN's Large Hadron Collider. In SBS it is less clear what instruments look like. Abbott (2011) argues persuasively that the humanist's tool is a well-stacked library, offering physical access to huge numbers of publications assembled according to a not too arbitrary system of classification. But there are other types of SBS researchers, empirical sociologists, psychological experimenters, and economic or demographic modelers among them. Not only do they need money to hire helping hands, they also developed and adopted real instruments over the course of decades: Questionnaires, coding handbooks, machines to process punched cards, devices for storing data as magnetic tapes, etc. Furthermore, assembling a group of people for a focus group interview needs an appropriate space, asks for utensils to record what has been spoken or to make use of Super 8 mm film, later replaced by video and more recently digital cameras. For field researchers it might be sufficient to possess a pencil and a notebook as devices, accompanied by the quintessential humanistic instruments: a trained brain and a good memory.

From a more systematic point of view, one could argue that established search strategies, methodologies, techniques, and finally exemplars also belong to the category of instruments. At the level of search strategies, SBS scholars can be divided crudely according to their inclination toward the average man, Quetelet's 'l'homme moyen,' on the one hand and the genius on the other hand. If one is committed to the first perspective, every single individual observed could be exchanged for another one (Igo, 2007), whereas in the opposite branch of scholarship, the researcher is looking for particularities, following an idiographic approach which has its vanishing point in the unparalleled individual, the great man of the old days. Ordinary SBS research happens in between these two poles, some of it based on what one could properly name an instrument, other lacking such independent existing gadgets. Most of the scholarly discussion on search strategies is located in a philosophical frame of references. Some German philosophers, for example, called their respective thinking 'philosophical anthropology' by referring to basic assumptions about mankind. Others debated nearly the same under the title of universals, or in cultural anthropology with regard to cultural relativism. All these contributions assume that a particular set of capabilities is demonstrated or even better possessed by all men and women.

Less abstract than search strategies are methodologies. The debates on methodology are dominated either by experts in

research methodology or philosophy of (social) science. Due to their competences and interests, they seldom study the historical trajectory of particular methodologies in detail, but rather their potential refinements or abstract justifications. A historical analysis of methodologies would accentuate the contingency of particular developments, by highlighting personal influences, philosophical or *meta*-theoretical fashions, and opportunity structures at particular cognitive microenvironments to detect the roots of novel methodologies or to identify which forces support continuity in once established routines (Bunge, 1998; Outhwaite and Turner, 2007). At this level of abstraction, methodologies are transformed into routine techniques of doing research, and what has been said about potential lanes of analyzing methodologies can therefore be applied (Platt, 1996; Steinmetz, 2005; Savage, 2010).

A particularly interesting phenomenon is the case of exemplars. Thomas S. Kuhn made them famous and drew attention to the fact that ordinary scholars very often imitate exceptional models (Kuhn, 1962). A serious history of such model studies which functioned as exemplars in particular disciplines for a particular period of time is a strong desideratum in the history of SBS (Lazarsfeld, 2011).

Switching the perspective of analysis from the instruments to their qualities, one can ask for the degree of adequacy of each instrument both in synchronic and diachronic perspective. Is a particular search strategy, methodology, etc., used only in particular microenvironments (such as departments, schools, research institutes, etc.) or is it dominant at the national or even international level? How did it happen that this routine was established locally, nationally, or internationally? A second question could be directed toward the lineage of a particular instrument: Have there been predecessors, and how have they been transformed into the new shape; did the advocates of the new tool quarrel with those who favored the old one, or did they ignore particular rivals? What has been said about competitors in time could also be applied to synchronic opponents (see Merton, 1996).

Institutions

Analyzing institutions is quintessential in furthering our understanding of what happens in science and scholarship. Opportunity structures (Merton, 1995) can be seen as the conditions that shape scholarship with regard to resources; opportunity structures emerge, diffuse, and differentiate over time and space. We can describe (1) the location where scholars exhibit their profession (ranging from stable cognitive microenvironments as departments to more temporary collaborations and encounters, (2) the audiences they address, and (3) the modes of governance to which they are subjected. (1) Up to now, both sociologists and historians of science investigated primarily units of relatively stable shape and paid less attention to the more fleeting opportunities to exchange ideas. Traditional academies did not play a big role in SBS, but research networks of the 'invisible college' type and occasional happenstances as the coming together of a class of fellows at one of the centers of advanced study, offering not only the 'leisure of the theory class' (Bell, 2000: 448) but serendipitous stimulation for each of them, deserve closer examination (Heilbron et al., 2008). The still underresearched forum where ideas were exchanged, evaluated, and further developed are publications, and journals in particular. These media deserve to be studied more deeply because they exhibit the assignment of status and reputation via peer review and direct the attention of the members of each discipline toward those contributions which need to be recognized. The procedures of peer review have been studied by scientometricians since decades, however poorly recognized beyond these circles, and have been quite recently more visibly debated (Lamont, 2009). Journals, through their development over time and changes in their policies caught the attention of only very few sociologists and historians of SBS (Besnard, 1979; Lepenies, 1981; Abbott, 1999), whereas encyclopedias of the social sciences are still waiting to become the subject of serious investigations, besides their obvious role in shaping the knowledge of the covered disciplines and exhibiting the distribution of the cultural capital within them. Translations are another instance of exchanging ideas and shaping the international migration of ideas, and recent attempts to analyze them demonstrate the fruitfulness of this kind of investigation (Pollak, 1986; Heilbron, 1999; Sapiro and Bustamente, 2009). Academic and non-academic publishing houses, their market (and, consequentially, book selection) strategies, their distribution policies and technologies further are crucial factors in shaping the gestalt of SBS.

(2) The addressed audience might be other academics only, the lay people, or clients, either from the private or the public sector of any society or state (Fleck et al., 2009; Fleck and Hess, 2014). Seeing addressees as clients points to their influence on what is at the core of scholarship, whereas looking at them as uneducated and unsophisticated audiences only invites to see the 'masses' vis-à-vis the known experts (Lazarsfeld et al., 1967; Halliday and Janowitz, 1992). The distance between those who do science and those who support them or pay for them varies in history, but at any given time any variant of scholarship is embedded in larger environments, offering the mandarins time and resources at different levels of generosity, stimulating or discouraging their striving for the truth (Ringer, 1969; Lepenies, 1988; Calhoun, 2007; Fleck, 2011).

(3) Since science policy decision makers are part of the audiences, too, there is some overlap of the modes of governance with the aforementioned audiences. However, but the power relationship is reversed: Scholars are on the receiving side and those who supply funds are in the position to dictate the rules, as it happened recently with the imposition of new public management's audit culture (Strathern, 2000; Münch, 2007, 2011). The widely debated Mode-2 perspective (Gibbons, 1994; Nowotny et al., 2001) has rarely been discussed with regard to developments in SBS (Albert, 2003; Kropp and Blok, 2011). Earlier instances of models of governance have been investigated both with regard to the role of the state in general (Wagner, 1990) and philanthropic foundations (Bulmer, 1984b; Fisher, 1993).

The increased interest in institutional thinking did not have sustainable consequences for writing the history of SBS so far. Both small-scaled (e.g., sabbatical, project research, teamwork, etc.) and large institutional frameworks have been researched only in the sociology of science, particularly in the world

polity approach (Drori et al., 2003, 2006). Even when small environments have been researched as, e.g., departments, the explanations for their rise and decline did not take into account the larger institutional settings, very much to the disadvantage of their results.

Contexts

Since the beginnings of sociology of knowledge and sociology of science, contextualization is the distinct feature of any externalist approach to study the texts of surrounding authors and/or the nontextual (political, institutional, etc.) environment. Galison (2008) rightly emphasized that we need a specification of the meaning and the range of the concept 'context' and its application in history of science and related fields of research. We will highlight only two types of contexts here, which affected the trajectory of SBS over the last two centuries. These are governance on the one hand and political regimes on the other hand. In addition to what has already been said with regard to the first, we want to draw attention to another feature: patterns of internationalization of SBS. Most analyses still follow the directions laid out by modernization theory since the 1950s. Patterns of diffusion and imitation accompanied by some pinches of cultural imperialism dominate most of the publications and this might be appropriate if the focus of one's analysis is on the macro-level of the science system: What has been labeled 'isomorphism,' the consolidation and following impact of the modern world polity and culture system on different branches of scholarship and institutions worldwide, is at the moment the most prominent approach (Drori et al., 2003, 2006). Several studies on the 'Americanization' of disciplines' theories and methodologies elsewhere could be mentioned here (Haney, 2008; comp. Heilbron et al., 2008). Another recent enhancement of contextualization is provided by putting globalization of science and scholarship on its head, to bring the contributions of peripheral scholars to the attention of scholars at the center (Patel, 2010) or offering insights from distinct patterns of a politics of academic autonomy (Beigel, 2013). The recent flourishing of behavioral economics could be mentioned as an illustrative record, where a disreputable empirical social research technique, experimentation, became prolific because of its application by sophisticated economists. Their longtime disregard for empirical research has been transformed into an asset because the experimenters were able to design their experiments ingeniously due to their theoretical preponderance.

The impact of political regimes on the SBS has been extensively studied for the Nazi case and its expulsion of mostly Jewish intellectuals (Coser, 1984; Ash and Söllner, 1996; Feichtinger, 2001; Fleck, 2015) and to a lesser degree for the communist world (Sparschuh and Becker, 1997; Keen and Mucha, 1994, 2006; Voříšek, 2012, 2011; Fleck and Hess, 2011). A recently blossoming branch of literature investigates the impact of the Cold War on the cognitive gestalt and social organization of SBS (e.g., Abbott and Sparrow, 2007; Cohen-Cole, 2009, 2014; Engerman, 2009; Erickson et al., 2013; Gerovitch, 2002; Mirowski, 2002, 2005; Robin, 2001; Rohde, 2013; Solovey, 2013; Solovey and Cravens, 2012).

Conclusion

The history of SBS is a field not yet fully established within academia. In addition, crucial differences in the quality and intensity of historical scholarship exist between the various SBS disciplines. Thus, any attempt to project a methodology for SBS historiography is probably most successful if it conceives of itself as a descriptive endeavor inspecting the existing historical literature, and not as an endeavor of philosophical thinking that attempts to logically deduct prescriptions for how to correctly write the history of SBS.

Abstract

The article discusses interpretations of the Mexican Revolution, focusing on the revolution's origins, armed phase, and postrevolutionary state building, along with the key themes anticlericalism, Cardenismo, international relations, indigenismo, women and gender, the Pax Priísta, and historical memory. It argues that populism, revisionism, and postrevisionism offer a useful way to categorize the main trends in a large and expanding body of scholarship. While scholarship has been influenced by new empirical data, and broader theoretical and methodological trends in the social sciences, it has also been (and will remain) strongly influenced by contemporary politics in Mexico.

The Mexican Revolution is difficult to define neatly in time, space, or in terms of its ideological content. It began in 1910, when the liberal reformer Francisco Madero campaigned for presidency, was arrested by the government, escaped from prison, and issued a call for rebellion on November 20. By May 1911, a revolutionary movement of middle-class reformers and dissident peasants had emerged around Madero to oust General Porfirio Díaz, who had ruled the country for all but 4 years since 1877. The revolution's end is harder to discern; it lacked a clearly defined vanguard or ideology, and worked differently in different parts of the country. However, the revolution defined Mexico's twentieth-century history; it mobilized unprecedented numbers, brought warfare, disease, and famine in its wake; inspired sweeping social reform and cultural experimentation; and created an official party-state that ruled Mexico for 71 years. Although Mexicans rarely saw their revolution as a model to be exported abroad, it provided a source of inspiration for other reformers across Latin America, and has produced an extensive body of scholarship in history and the social sciences, both in and outside of Mexico.

Interpretations

It is useful to group scholarship into three broad interpretations. Populist accounts tended to portray the revolution as a popular, agrarian struggle that toppled the dictator Díaz, consolidated Mexican sovereignty, and delivered substantial gains for the masses, particularly during the presidency of Lázaro Cárdenas (1934–40). After the heightened suppression of students in and after 1968, revisionist perspectives predominated, which downplayed the revolution's popular support and accomplishments, and emphasized the continuities between the old Porfirian order and the new revolutionary state (Baily, 1978). Since the 1990s, postrevisionists have generally sought to reconcile these perspectives, emphasizing the dynamic relationship between revolutionary leadership and popular groups, state and civil society, and the variety of experiences in Mexico's different regions (Joseph and Nugent, 1994). These changes in interpretation have been shaped by (but are not reducible to) larger trends in historiography. Particularly important has been the proliferation of regional and local case studies first pioneered by González (1974). Like elsewhere, the 1980s and the 1990s also saw a turn away from perceived economic reductionism and a growing interest in cultural identities and language (Joseph and Deans-Smith, 1999), although the cultural turn in Mexican historiography now appears to have largely run its course. The best new scholarship combines deep empirical research with a notable theoretical and methodological eclecticism well suited to the revolution's sprawling, multifaceted character.

Origins

Most historians have sought the origins of the revolution in the profound changes Mexico underwent during the Porfiriato – the period of Porfirio Díaz's rule. Historians have traditionally seen the Porfiriato as a time of exclusionary, foreign-dominated capitalist development, overseen by an antinational and increasingly authoritarian political elite. The past two decades have seen a burst of new, impressively detailed research on the Porfirian political economy, which has questioned aspects of the old story. Despite integration into global markets, the domestic market was large and important; the state played a crucial role in economic development, not only as a conduit for cronyism and corruption (although this was crucial) but also through coherent policies of fiscal reform and a moderate protectionism. New research has painted a complicated picture of the effects of liberal laws on communal peasant land; some communities kept lands, some litigated against surveying decisions, and some sought to take advantage of liberal laws to privatize land on locally acceptable terms. Overall, newer studies are less confident than older works in linking the problems of the Porfirian political economy to the causes of the revolution, and tend to focus instead on an ossified and exclusionary political system (Riguzzi, 2009). Recent work on nineteenth-century popular liberalism has complemented this turn to political causes in some ways, showing the long tradition of peasants mobilizing for national goals and demanding local autonomy (McNamara, 2007).

The Armed Phase

Madero's movement inaugurated 10 years of upheaval and warfare – what historians usually refer to as the revolution's armed phase from 1910 to 1920. Madero proved an ineffective president: on one side, he faced the old Porfirian establishment, particularly the army, which he largely left intact; on the other, he faced frustrated former allies who expected more radical land and labor policies. Eventually, Madero was toppled by a counterrevolutionary coup and General Victoriano Huerta – whose sanguinary reputation earned him the nickname of the jackal – took power in February 1913. Huerta assassinated Madero and militarized the country, but only succeeded in fueling more rebellions; in July 1914, Huerta was toppled by a diverse coalition of revolutionary forces hailing from different regions of the country.

Between, 1915 and 1920, different revolutionary factions then fought among themselves for control of the national government. In the southern states of Morelos, Puebla, and Guerrero, Emiliano Zapata led his army of peasant villagers. Pancho Villa's movement emerged in the northern state of Chihuahua, and reflected the social complexity of northern society: miners, cowboys, fiercely independent communities from the sierra. The Constitutionalists were based in the northern states of Coahuila and Sonora, and were generally more middle-class and well connected than the Zapatistas and Villistas; indeed, the Constitutionalist leader Venustiano Carranza had been state governor of Coahuila (Brading, 1980). Despite the Zapatistas and Villistas joining forces, after a series of decisive battles in the central Bajío region in the summer of 1915, the Constitutionalists gained the ascendancy. Constitutionalist General Álvaro Obregón was a formidable military strategist, and one whom Villa appeared to underestimate. In 1919, Constitutionalist forces ambushed and assassinated Zapata in Morelos. Villa's forces were gradually reduced to small-scale guerrilla warfare; Villa was permitted to retire to a hacienda, but was later assassinated in 1923. In 1920, the Constitutionist faction itself fragmented; a powerful clique of revolutionaries from the northwestern state of Sonora, led by Obregón, rebelled against Carranza and took power. Carranaza fled the capital, only to be assassinated in a small village in the sierra of Puebla.

The revolution meant different things to different people. Madero had initially focused on the need for political reforms, clean elections, and good government. However, other groups soon emerged seeking more radical policies. The Zapatistas sought land, local autonomy, and an end to central government abuses, particularly electoral imposition and the draft. The Villistas also adopted the cause of land reform, although Villa delayed most land grants until after the fighting had finished (Katz, 1998). The Constitutionalists were far less interested in land reform. However, some Constitutionalists were radical in their willingness to ally with (and offer concessions to) organized labor, and in their determination to remove the Catholic Church's influence on public life. In 1916–17, the Constitutionalists met to draft a new constitution. The Constitutionalists' need to undermine support for Villa and Zapata, and the divisions within their own ranks, ensured that the resulting document was a good deal more radical than Carranza intended. True to Madero's original impulses, the constitution included many familiar liberal democratic elements: regular elections, division of powers, and civilian control of the military. However, Article 27 also gave the government ownership of Mexico's land and subsoil, and the right to distribute these resources for the good of the nation. Article 133 made the constitution the first in the world to guarantee workers' rights, including the right to strike and the 8-h day. Finally, the new constitution built on and extended nineteenth-century liberal anticlericalism; Article 3 secularized primary education and forbade political comment by religious institutions, and Article 130 allowed state governments to control the number of clergy in the country.

(Post)revolutionary Reform and State Building

After 1920, successive administrations went about gradually rebuilding a national government and economy, and selectively enacted reforms from the Constitution of 1917. From 1920 to 1934, the Sonoran faction ran the government, led by Generals Obregón (President, 1920–24) and Plutarco Elías Calles (President, 1924–28). The Sonorans defeated military rebellions in 1923–24, 1927, and 1929, and obtained recognition and loans from the US government. They experimented with new forms of mass politics but, despite much talk of socialism and bolshevism, remained firmly committed to capitalist development and pursued land reform in piecemeal fashion. In 1928, they also founded a national party that claimed to be the true heir of the revolution. This party ruled the country in one form or another from 1929 to 2000, and has returned to the presidency once more in 2012.

Few scholars would maintain that the official party still represents the revolution in any meaningful sense. However, debate continues about quite when the wave of political mobilization, social reform, and cultural experimentation unleashed by the revolution definitively receded; or, indeed, if the wave was ever more than a puny ripple. Reflecting this uncertainty, many historians refer to the decades after 1920 as the postrevolutionary period, while others would prefer to label it a continuation of the revolutionary process. The choice of an ending largely depends on what aspects of the revolution are emphasized. Focusing on political legitimacy, some would extend the revolutionary period until the dramatic student protests of 1968, although the degree to which 1968 really changed Mexicans' perception of their government is much debated. Some would move the ending to the debt crisis of 1982, when the party's model of economic nationalism and state-led industrial development collapsed (Beezley, 2007). However, if one focuses on what really made Mexico's experience revolutionary and distinctive in Latin America – radical attempts to redistribute property and political power – it is convincing (and conventional) to date the end to around 1940. In the 1940s, a new, more civilian generation took over the party, tacked rightward, and pursued probusiness policies. In 1946, the party adopted an odd but entirely appropriate new name: The Party of the Institutional Revolution (Partido Revolucionario Institucional, PRI). Regardless of which threads are focused on, it is clear that the formation of the new regime was very protracted, geographically uneven, and conflictive.

Anticlericalism

One key source of conflict was the relationship between the new regime and the church. During the constitutional congress of 1916–17, anticlericalism provoked by far the most vociferous debate among the 217 delegates. Conflict with the church came to a head after Calles enforced the constitution's new anticlerical provisions. In 1926–29, thousands of Catholics in the center-west of the country rebelled against the government in a movement known as the Cristiada. For decades, the government portrayed the rebels as poor, superstitious peasants duped by reactionary landlords. Jan Meyer's (1976) impressively researched study countered this official history and portrayed the movement instead as a popular, religious movement against an authoritarian state, and detailed the bloody counterinsurgency by which the government contained the rebellion. Recent studies have allowed for a more nuanced understanding of the religious conflict, revealing the dynamic, changing quality of popular religion, the competing varieties of revolutionary anticlericalism, and how local rivalries between villages helped determine which side peasants ended up supporting (Butler, 2007). The government eventually defused the rebellion by brokering a deal with the Catholic hierarchy in 1929. However, conflict between the revolutionary state and Catholic groups continued to flare up at the local level throughout the 1930s, and even after the moderate, reportedly pious Manuel Ávila Camacho became president in 1940 (Smith, 2012).

Cardenismo

The presidency of Lázaro Cárdenas (1934–40) has long been a focal point for different interpretations of the revolution, particularly its relationship with popular groups. Cárdenas emerged in populist accounts as the culmination of revolutionary radicalism, he broke the backstage power the Sonoran clique, oversaw a sweeping land reform, supported organized labor, struck a blow for economic sovereignty by nationalizing the oil industry in 1938, and turned the official party from a talking shop for the revolutionary elite into a mass, corporate party with sectors for peasantry, workers, middle classes, and the military. This narrative was challenged by revisionists, who portrayed Cardenista reform as a sophisticated attempt to divide and co-opt the masses, deepen the internal market, and consolidate capitalist development. What many accounts had in common was the tendency to see Cardenismo creating a powerful, centralized, and stable state. Knight (1994) provided what has proven to be a highly influential synthesis; he argued that Cárdenas' project represented a radical attempt to create a more equitable and inclusive society (and was correctly understood as such at the time), but was limited by state weakness and growing political opposition. Many of these arguments have found support in later studies of the right-wing and regional opposition (Fallaw, 2001). In the 1930s, federal public education was shaped by regional power brokers, and by peasant communities themselves, who rejected or adapted aspects of the state's message of anticlericalism, class consciousness, and social reform. However, in some communities at least, public education did help stabilize Mexican politics by encouraging people to use a shared revolutionary discourse and party institutions to make demands of the government (Vaughan, 1997).

International Relations

The revolution was nothing if not a defense of national sovereignty, and an extensive literature has developed on Mexico's relations with the rest of the world. During the armed phase of the revolution, the US government repeatedly intervened in Mexico. However, historians have disagreed about how much emphasis to place on the US role. For Hart (2002), the expansion of US capitalism during the Porfiriato was a central cause of the revolution, while US interventions were decisive in defeating the revolution's more radical factions. However, economic nationalism rarely excited fierce popular support, and the US government's vacillating and counterproductive interventions were less important than domestic conflicts in shaping the outcome of the revolution's armed phase. The US ambassador to Mexico, Henry Lane Wilson helped orchestrate the counterrevolutionary coup of 1913, although he acted on his own initiative and infuriated President Woodrow Wilson. From April to November 1914, US marines occupied the port of Veracruz, preventing the arrival of arms shipments to Huerta. The US government then cultivated relations first with the Villistas, and then the Constitutionalists, and in 1916–17, sent a punitive expedition into northern Mexico to pursue the Villistas; the expedition failed and further antagonized the Constitutionalists who saw it as an affront to Mexican sovereignty (Knight, 1988). After 1920, tensions with the US government focused on the oil industry, debt, and reparations for damages. The Bucareli Accords of 1923 settled these issues and allowed a modus vivendi to resume, although tensions flared again periodically when Calles offered support for the Nicaraguan nationalist Augusto Sandino, and again in 1938, when Cárdenas nationalized the oil industry. After the 1940s, as revolutionary radicalism waned, relations between the US and Mexican governments became notably cordial. During the Second World War, Mexico provided mineral resources and bracero labor to fuel the war effort, although some tensions remained over the terms military collaboration. While US–Mexican relations have dominated the field, Katz (1981) pioneered a more multilateral approach. From the 1910s to the 1940s, European powers jockeyed for influence in Mexico and Mexico sometimes succeeded in using this competition to deflect US influence (Schuler, 1999). In recent decades, historians have also sought to move the focus away from diplomacy, and incorporate culture, tourism, and travel into the study of Mexico's international relations (Delpar, 1992).

Indigenismo

The revolutionary regime's new stance toward indigenous peoples fascinated foreign observers in the 1920s and the 1930s and has provided another enduring theme in the historiography. Much of the literature has analyzed indigenismo – the revalorization of indigenous culture – as an

artistic and esthetic phenomenon. In the nineteenth century, Mexican liberals sometimes celebrated the achievements of old pre-Colombian civilizations, but they generally disdained or ignored contemporary Indian peoples and cultures. The revolutionary regime sponsored the murals of Diego Rivera replete with new images of indigenous history and customs and encouraged a vogue for indigenous folk art and music. Other studies have focused on social policies, particularly education, and their reception in indigenous communities. Interpretations of official indigenismo have echoed broader shifts in historiography, ethnography, and political science. In the 1970s, Mexico witnessed a major backlash against official indigenismo as a new generation of anthropologists, indigenous intellectuals, and leaders condemned it as a thinly disguised project of assimilation. This was in many ways a powerful critique; beyond the murals and exhibitions, indigenous-state relations could still be conflictive; in 1927, the Sonoran regime used its new military aircraft to drop bombs on rebellious Yaqui Indians; by the 1940s, assimilation had clearly became the objective of official indigenous policy. However, indigenismo was, initially at least, a multifaceted phenomenon, shaped by the press, artists, the state, transnational intellectuals, and even military leaders. It consequently contained divergent attitudes and ideas, and sometimes allowed indigenous leaders to make political demands and claim material benefits in new ways (Lopez, 2010; Dawson, 2004).

Women and Gender History

The past two decades have also seen a steady growth in studies of the revolution's effects on women and gender norms. Scholars traditionally viewed the revolution as a quintessentially macho event, a revolution by and about men. Historians first sought to recover the history of Mexico's early feminist movement, which received support from some Constitutionalist leaders such as Felipe Carillo Puerto, and women's varied roles in revolutionary warfare as soldaderas: camp followers, spies, sometimes soldiers, and officers. Scholars have now broadened the focus, exploring women's experiences in the home, in the schoolhouse, on the factory floor, and in the red-light zone. They have also charted the unprecedented growth in the 1920s and the 1930s of women's political organizing, both within dissident Catholic and revolutionary groups. Women's political objectives and tactics varied; some emphasized political rights, while others emphasized social citizenship; some groups demanded rights on the basis of equality, while others adapted maternalist arguments based on women's essential qualities. The overall picture remains one of enduring patriarchy, albeit a patriarchy that was reshaped – or modernized – in important ways. Women's organizing shaped the design and implementation of new social and welfare policies, was central to social movements across political spectrum, secured new administrative and political posts for women, and eventually led to female suffrage in 1953 (Olcott et al., 2006; Mitchell and Schell, 2007). While new studies reveal a great deal about gender relations in the period, the study of men as gendered subjects remains relatively underdeveloped.

The Pax Priísta: 1940s–60s

The two decades after 1940 have usually been seen, for better or worse, as the heyday of the new regime's stability and control – a Pax Priísta. In the past decade, as archives have opened, and the weakness of the Cardenista state has became more apparent, historians have increasingly turned their attention to this period. Few challenge the idea that government radicalism petered out after the late 1930s. However, new studies have given us a much better understanding of the kind of political system the revolution ultimately bequeathed. Before the past decade, most accounts of the 1940s and the 1950s were written by political scientists, who presented synchronic analyses of a stable political system centered on the corporate party and a mighty presidency (Schmidt, 2001). In the past decade, historians have increasingly emphasized the limits of state power: state institutions were riddled with caciquismo; president and party had to contend with regional business interests, independent military officers, and an enduring tradition of popular protest against everything from corruption and taxation, to electoral fraud and conscription. There has been a related renewal of interest in political violence in midcentury Mexico. While older studies celebrated how the regime professionalized the rebellious army of the 1920s and pushed it back into the barracks, new accounts show the continuing importance of the military in policing and repression. Regional studies show that politics under the PRI were often a rough business, punctuated by pistolerismo, collective repression, riots, and small insurgencies and counterinsurgencies (Rath, 2013; Gillingham and Smith, 2014). While this work on the Pax Priísta helps us understand how the revolution came to an end, it has also been influenced by shifting perceptions of contemporary Mexico, as the drug war has encouraged scholars to reexamine earlier assumptions of stability and control.

Historical Memory and Conclusions

Indeed, the debate over the historical meaning of the revolution has been (and remains) an integral part of Mexican politics. The scholarly revisionism in the 1970s had long roots. In the novels of Azuela (2008) and the murals of Orozco, the revolution emerges as chaos, violence, and hypocrisy; from the very beginning, conservative Catholic critics of the revolution abounded, while many others criticized the revolutionary party's betrayal of liberal democracy, such as José Vasconcelos during his 1929 presidential campaign. Confronting these critical voices, the new regime made great efforts to create an official myth of the revolution as a unifying event that brought Mexico peace and justice under the auspices of the revolutionary state. The government disseminated its version of history through school textbooks and the mass media, censored the national press, and created a plethora of new holidays and parades such as Revolution Day on 20 November. While Zapata, Villa, Carranza, and Cárdenas all had their differences while alive, they were buried together at the huge Monument to the Revolution in downtown Mexico City (Benjamin, 2000). Of course, we cannot assume that people swallowed the stuff of official myths whole, although the

history of how people responded to official myths is difficult to write and few studies have attempted it.

Many observers argue that whatever credibility and appeal this official version of history enjoyed was ebbing away by the 1980s. And yet, the revolutionary tradition was not entirely spent. While the PRI gradually began losing control over politics and public discussion, opposition groups continued to criticize the regime in the name of the revolution. In 1987, a group of left wingers split from the PRI, led by Lázaro Cárdenas' son Cuauhtémoc, and claimed the heritage of the radical 1930s. In 1994, peasants in Chiapas rebelled against government corruption and the end of land reform, and called themselves Zapatistas (O'Toole, 2011). In 2000, the PRI lost the presidency to the center-right Party of National Action (Partido Acción Nacional, PAN). The PAN would probably rather have ignored revolutionary history altogether, but in 2010, they found themselves in charge of organizing public commemorations of the centenary of the revolution. They responded by creating public ceremonies, speeches, dances, and light shows, which celebrated aspects of the revolution they liked (liberalism, Madero) and elided those they did not (agrarianism, anticlericalism). During the 2012 election campaign, the PRI at once claimed to have broken with the corruption and illiberal errors of the past, and invoked its reputation for stability and constructive material development; PRI posters across Mexico City asked citizens to remember which party had brought peace to Mexico and built the subway system.

Scholarship on the Mexican Revolution has been shaped by new empirical data, new methodologies – particularly the turn to regional history – and changing theoretical perspectives, and we know a great deal more about revolution in all its complexity than we did two decades ago. However, the topic is still far too recent, with far too profound a legacy to be only of scholarly interest. With the return of the PRI to power in 2012, the intimate connection between contemporary political debate and the questions people ask about the revolution and its history is likely to continue for some time to come.

Abstract

This article provides a brief overview of the history of microeconomics, starting from the late eighteenth century when its key foundations were laid. Without intending to be comprehensive, the article outlines landmarks and milestones in the building of the basic principles of today's knowledge, highlighting challenges faced and open questions. Focus is on the contribution of each historical phase to the understanding of two foundational issues in microeconomics – the theory of individual economic decision making and the market mechanism as a coordinating device. At the end, the article discusses the current state of microeconomics and recent tendencies.

Introduction

Microeconomics stands as one of the two main pillars of today's economic science, the other being macroeconomics. Microeconomics seeks to understand how individuals, households, and companies make decisions; the factors that shape these decisions; and how these decisions affect others. Its object is decision making at low, or micro, level, in contrast to macroeconomics, whose focus is the behavior of national aggregates such as gross domestic product, inflation, and unemployment.

At the heart of microeconomics is a social and scientific 'mystery.' In modern market economies characterized by private property and freedom, decisions to produce, sell, work, buy, and consume are made by multiple individuals, households, and companies autonomously and independently from one another; each actor chooses under limited, or even inexistent, knowledge of the choices of others. Yet someone's decision to buy, say, a pint of milk can only translate into an actual purchase if someone else simultaneously decides to sell a pint of milk. So if buyer and seller do not coordinate *ex ante*, how can their decisions engender actual, mutually beneficial transactions, rather than result in disappointment and frustration? The market mechanism is the device that accomplishes this result: by establishing the relative price of goods and factors, it informs individual decisions, adjusts the quantities traded, and achieves *ex post* coordination. Microeconomics, through the supply-and-demand framework of analysis, looks at how this happens. It also studies the effects of institutions such as government regulation and taxation on individual choices and market outcomes.

In essence, microeconomics is as old as economic thought itself: Classics in the eighteenth and nineteenth centuries laid out the theoretical elements that have progressively molded economists' understanding of individual decision making and the market mechanism. Yet the 'micro' label and the representation of microeconomics as a separate enterprise, explicitly distinct from macroeconomics, emerged much later. According to Humberto Barreto (2012), its first traces are in a 1933 article by Ragnar Frisch for whom the micro approach would "try to explain in some detail the behavior of a certain section of the huge economic mechanism," while the macro would instead "give an account of the fluctuations of the whole economic system taken in its entirety" (Frisch, 1933: p. 2). The work of John M. Keynes (1936) in those same years, with its strong focus on aggregate relations and an extremely simplified representation of individual behaviors, popularized the belief that the macro level of analysis differs in nature from the microlevel, and contributed to further differentiating the two subdisciplines.

Since then, it took another 50 years before economists formally acknowledged the micro–macro taxonomy. In the classification of subject fields of the *Journal of Economic Literature*, a reference for the profession worldwide, micro- and macroeconomics were subsets of a broad 'theory' category in the original 1960 version, and were brought up a level and highlighted as major independent categories in a substantial revision of the system in 1991 (Barreto, 2012). They remain two major areas today, allowing the development of new or renewed subfields within them. The teaching of economics has followed suit, with current curricula typically separating micro- and macroeconomics courses, both being part of the core training of new economists.

Perhaps ironically, a parallel movement has been increasingly blurring the distinction between the micro and macro approaches. Economists have grown more and more uncomfortable with the idea that different theoretical principles apply to the study of individual decisions and the aggregates that (ultimately) result from them. Since the late 1980s the 'microfoundations' movement in macroeconomics, championed by Robert Lucas (born 1937), aims to reconcile these two traditions and rebuild macroeconomics so as to make it consistent with the principles of microeconomics.

This article provides a brief overview of the history of microeconomics, starting from the time in which its key foundations were laid, although the 'micro' terminology was not yet in use. Despite the interest of the early literature, which dates as far back as antiquity and the Middle Ages (see, e.g., Hutchison, 1988), a detailed account of it would be beyond the scope of this article, and the more traditional convention of starting from the late eighteenth century is followed. The article overviews historical developments since then, without intending to be comprehensive, but aiming only to outline landmarks and milestones in the building of the basic principles of today's knowledge, highlighting the challenges faced and the questions that remain open. Focus is on what each

historical phase contributed to the understanding of the two foundational issues in microeconomics – namely, the theory of individual economic decision making and the market mechanism as a coordinating device. At the end, the article discusses the current state of microeconomics and recent tendencies, again distinguishing between the study of individual behaviors and the market mechanism.

The Origins: Self-Interest and the 'Invisible Hand' in Adam Smith

The Scottish philosopher Adam Smith (1723–90) is widely regarded as one of the founders of economics; though not alone in this enterprise, he exemplifies at best the novelty and relevance of eighteenth-century thought in defining what would become the basic principles of microeconomics. In his *Wealth of Nations* (1776), Smith was the first to explicitly characterize individual economic behavior as *self-interested* behavior, admitting that it is people's desire for a gain that explains work, production, and ultimately the existence of an economic system:

> It is not from the benevolence of the butcher, the brewer, or the baker that we expect our dinner, but from their regard to their own interest. We address ourselves, not to their humanity but to their self-love, and never talk to them of our own necessities but of their advantages.
> (Smith, 1776/1981: pp. 26–27)

The idea that businesspeople act to satisfy their self-interest may seem dauntingly simple, and to some extent brutal in its apparent amorality. Yet over time, it has proven fertile in informing economists' imagination and their capacity to explain individual decision making. It is not a sheer defense of selfishness – in present-day parlance, one would simply say that people respond to *incentives*, that is, advantages or gains that can derive from given decisions or actions. By and large, modern microeconomics assumes that individuals' motivations when they make decisions are their expected gains by those decisions.

But Smith, a moral philosopher, could not neglect motivations other than self-interest in shaping economic decision-making. Indeed his self-interest must be understood in conjunction with another behavioral principle, that of *sympathy* between human beings who, by putting themselves imaginatively in the place of others, understand their feelings and expectations and are moved to act accordingly (e.g., to give to those who are in need). While Smith's critics initially opposed sympathy and self-interest, today's scholarship sees them as two instances of a common framework for thinking about human behavior, in which the individually centered, self-interested component is accompanied by an interpersonal dimension, so that it becomes possible to account for various forms of behavior, from gain-seeking actions to philanthropy. Reconciliation of these two aspects of Smith's thought makes him the father of microeconomics in a broader sense: A recent trend in today's research on economic decision making (see below) tends to explicitly integrate forms of prosocial behavior into the analysis.

Incidentally, the Smithian model of individual behavior had the merit of supporting an egalitarian perspective in the nineteenth-century political debates. If the same scheme holds for all individuals, they are all equal and have the same capacity for decision making; observed differences, if any, depend on chance and history. This egalitarian view was shared by most economists of the time and strongly contrasted the (then also widespread) hierarchical stance that regarded the lower classes of society and supposedly 'inferior' ethnic/racial groups as less capable of making decisions and thus in need of guidance (Peart and Levy, 2005). Interestingly, the infamous 'dismal science' designation of economics was originally an accusation against economists' antislavery orientation, resulting from their belief that all humans are equal (Levy, 2001).

Smith's work also contributed to shaping economists' view of the market as a coordinating device that ensures, *ex post*, that individual decisions are consistent with one another and generate an orderly result. Smith's 'invisible hand' metaphor has often been recognized as an effective representation of this mechanism:

> by directing […] industry in such a manner as its produce may be of the greatest value, he [man] intends only his own gain, and he is in this, as in many other cases, led by an invisible hand to promote an end which was no part of his intention. By pursuing his own interest he frequently promotes that of the society more effectually than when he really intends to promote it.
> (Smith, 1776/1981: p. 456)

Because individuals are not isolated but part of a larger human community, their actions have unexpected or unintended consequences at the system level. Individuals take into account only their self-interest, yet their choices affect others and trigger a chain of interactions that eventually affect the society as a whole, well beyond their original intentions. Strikingly enough, Smith argues that this spontaneous process does not lead to chaos but to harmony: Self-interest may not seem a noble motivation, yet it triggers consequences that benefit society even more than those arising from benevolence. Thus, there is no need for a strong state power that would impose social order from above, as had been argued by Thomas Hobbes (1588–1679). The idea of unintended consequences and the possible reconciliation of individual self-interest and social good, first articulated by Smith, have been at the core of subsequent microeconomic reflection – which is another reason why Smith is credited as a founder of the discipline.

Early Developments: Marginalism, Supply-and-Demand, Formalization

To further develop Smith's approach, economists faced the formidable problem of how to operationalize the principle of self-interested action so as to apply it to the solution of concrete economic problems. They first thought about it in terms of the self-interested businessperson who makes production-related decisions: In his *On the Principles of Political Economy and Taxation* (1817/2004), the highly influential British writer David Ricardo (1772–1823) discussed how cost-effective substitution of machinery for workers, or of imports for nationally produced

goods through international trade, affects a firm's profits and workers' welfare. Ricardo's writings hardly touched on the study of household and consumer behavior, though: As many economists of the time, he was mainly interested in production forces, working conditions, and their differential impact on income distribution. Emphasis was on the effects of the whole economic system on individual behavior, rather than the reverse, and a fundamental heterogeneity distinguished economic agents – consumers vs firms. While the latter were already envisaged as cost-minimizers or profit-maximizers, placing emphasis on how they acted for their own advantage, less attention was drawn to the individual decisions of the former, and demand was mainly seen as an aggregate rather than an individual construct, for example, by assuming that population growth largely determines demand for food.

Even the authors who, following developments in philosophy and psychology, introduced the notion of 'utility' to account for the pleasure and pain that consumers derive from goods, found it difficult to integrate it into economic models. Utility initially appeared as a qualitative, subjective construct devoid of any objective, quantifiable attributes – very different then from the firm's profit or income, which centuries-long advances in accounting enabled to measure in straightforward way. The solution came in the mid-nineteenth century, from reinterpreting utility not as an absolute but as a relative magnitude, varying from one individual to another and for each individual, depending on the available quantity of a good. It turned out that measurability and quantification were not even necessary, insofar as utility could be expressed as a variable or a function of other variables, allowing comparisons (larger/smaller, more/less, positive/negative, etc.). One could thus distinguish the total amount of utility from 'marginal' utility – namely, the change in the level of utility that results from a given increase in the quantity of the good. Marginal utility was thought to diminish with the quantity consumed, reflecting the capacity of individuals to order the possible uses of successively acquired units: For instance, one would reserve the first gallons of water for drinking and the successive ones for personal hygiene, for housekeeping, and finally for watering plants. In passing, this assumption solved what earlier thinkers considered a paradox – the fact that useful goods such as water or air have low market value: The reason is their abundance, which means that the last increment in quantity generates an extremely small increase in utility. These results suggested an interpretation of self-interested behavior in terms of attempts to raise one's utility to its highest possible level and were obtained independently, in 1871–74, by William S. Jevons (1835–82) in Britain, Carl Menger (1840–1921) in Austria, and Léon Walras (1834–1910) in Switzerland.

The importance of thinking in terms of marginal variations rather than total magnitudes proved so useful to account for utility and demand that it was subsequently extended to supply. In fact, notions of marginal productivity and marginal cost of production, as opposed to total productivity/cost, had already been introduced, but in a patchy fashion; they were refined and generalized in the 1890s by, among others, John B. Clark (1847–1938), Philip H. Wicksteed (1844–1927), and Knut Wicksell (1851–1926). Marginal reasoning seemed so important that the economic thought of this time period is often referred to as *marginalism*.

On the coordinating mechanism, emphasis was increasingly placed on the symmetry of supply-and-demand factors and on the resulting market equilibrium. While Ricardo had stressed supply factors in the determination of prices and quantities traded, the mid-nineteenth century developed a view according to which individual demand and supply are derived, respectively, from agents' calculations of utility (for consumers) and profit/cost (for firms), and market supply and demand are obtained by aggregating all individual values. When market supply equals demand, the market is in equilibrium – that is, the decisions of all households and all firms are consistent with one another. The French mathematician Antoine-Augustin Cournot (1801–77) was the first, as early as 1838, to illustrate these principles with the help of price–quantity diagrams in which the demand of a good decreases, and the supply increases, with its price; The intersection of the supply-and-demand schedules identifies equilibrium, that is, a price at which supply equals demand and the market clears. This 'partial equilibrium' approach, focusing on the study of a single competitive market, was further developed and popularized a few decades later in England by Alfred Marshall (1842–1924); it is now a standard part of undergraduate microeconomics education.

The advantage of Marshall's partial equilibrium approach is that it provides a tractable framework to study the relationship between price and quantity; however, it is based on the restrictive assumption that changes in the price of a good affect the quantity of that good only, disregarding the possibility that a variation in the price of a good will impinge on the demand and supply of substitutes and complements of that good too. Hence, it can be taken at most as an approximation, not as a rigorous analytical device. A rival view focusing on interdependencies among markets was simultaneously developed by Walras (1874/1977), who represented economic agents that allocate their budgets to the purchase of multiple goods so that changes in the market price and/or quantity of one good are likely to have repercussions on the markets for other goods. His notion of 'general equilibrium' which would inform large parts of microeconomics, is directly derived from this view and corresponds to a situation in which supply equals demand on each market, so that all clear simultaneously.

A derived question is whether and how actual trade practices will drive prices and quantities toward equilibrium. Marshall and Walras provided different answers, consistent with their respective views. Walras (1874/1977) proposed a model of auctions in which at given prices, all traders declare the quantity of each good that they wish to buy or sell at those prices; if with these quantities, supply equals demand on each market, then this is the general equilibrium and trade takes place; if not, prices are adjusted in such a way that they diminish where supply exceeds demand and increase in the opposite case; at the new prices, traders announce again the quantities that they wish to buy or sell, and the process ('tâtonnement') starts again, until equilibrium is reached. In short, transactions take place simultaneously, at equilibrium only, so that the same prices apply to all traders. Instead, Marshall (1920) had in mind a sequence of bilateral transactions on a single market, in which each pair of traders negotiates a price and each transaction withdraws some units from the market so that lesser quantities are available for later

trades – in other words, the conditions under which traders negotiate are altered at every step. Such changes gradually dampen price adjustments until they reach the level that corresponds to the intersection of supply and demand. Here, transactions occur sequentially, in disequilibrium, at prices that may differ from a pair of traders to the other. These different approaches strongly affected later developments (see below).

These theoretical developments, often referred to as 'neoclassical' economics (in contrast to Ricardo's 'classical' theory), accompanied a growing tendency to *formalization*. Deeply intertwined with the development of microeconomic thought since its early phases, formalization is an approach to theory-building which, starting from the definition of theoretical constructs and of linkages between them, derives logical conclusions from given premises. In this sense, formalization is an abstract process and must be distinguished from *quantification*, or the systematic effort to measure reality for purposes of business or policy intervention, rather than theory-building, for instance by counting the population in a census. While quantification was already well under way at this time, it was formalization that needed to be advanced. Writing in its defense, Jevons claimed that "The data are almost wholly deficient for the complete solution of any one problem," yet "we have mathematical theory without the data requisite for precise calculation" (Jevons, 1965/1871). Yet despite its growing importance, formalization was still far from being prominent at the end of the nineteenth century, when many economists still privileged the verbal form and some overtly criticized the use of mathematics, the most prominent example being the German Historical School. It was only in the mid-twentieth century, after the emergence of microeconomics as a distinct theoretical enterprise, that formalization became a standard practice.

Maturity: Constrained Optimization and Market Equilibrium

The theoretical elements laid out in the nineteenth century went through further elaboration and systematization in the first half of the twentieth century, when neoclassical microeconomics blossomed and eventually arose as a major subdiscipline in conjunction with macroeconomics. The concept of utility was refined and utility gradually came to be understood as rational, purposeful behavior – choosing the best possible means to achieve one's ends, an interpretation that deprives utility of any identification with self-interest narrowly interpreted, and even with pleasure, pain or any other emotions and feelings. Consistency in choices turned out to be all that was needed, and the microeconomic paradigm that eventually emerged refrained from making psychological assumptions. This more neutral interpretation of utility came to dominate economics, notably through the *revealed preference* approach (Samuelson, 1938) which enabled application of the model to a variety of settings and behaviors (including non-selfish ones and altruism).

Consistency involves the optimizing behavior of agents under some constraints (budget for consumers, technology for firms). Progressively, the constrained maximization model was extended to the study of all individual decision units, on both the demand and the supply side of the market, becoming the basis of all analyses of individual economic behavior. The contribution of Paul Samuelson (1915–2009) was essential to these developments and mainly consisted in rewriting many problems of economics as maximization problems, with extensive use of mathematics. Samuelson's effort to show that apparently diverse subjects have the same underlying structure and can be treated with the same mathematical tools defined the core of what came to be known as microeconomics, and gave it unprecedented unity and coherence. Higher abstraction and technical difficulty, however, were the price to pay for increased scope and greater logical coherence – making the field inaccessible to wide audiences and hard to communicate outside a narrow circle of specialists.

With time, these revisions proved successful in that they made constrained maximization so powerful that it began to be thought of as a basis for understanding all human behaviors – not just those traditionally regarded as falling within the realm of market transactions. The work of Gary Becker (1930–2014), in particular, is founded on the idea that individual behavior follows the same fundamental principles in different areas, so that the same explanatory model – microeconomic optimization – should always be applicable. Becker thus extended the sphere of microeconomic analysis to the study of new areas, ranging from crime and discrimination to marriage and the family (Becker, 1992). Becker's analysis initially raised many eyebrows, but gradually came to exert a huge influence on the economics profession as well as on neighboring disciplines.

The optimization model was not beyond dispute, though: At least since the 1950s, Herbert Simon (1916–2001) and others contended that actual decision makers lack the cognitive capacities to solve maximization problems and rather content themselves with 'satisficing' behavior, choosing options that are not optimal but make them happy enough. Along these lines, they developed a 'bounded rationality' approach as an alternative to the seemingly strong rationality requirements of the individual maximization model. Yet it was difficult to identify universal principles enabling to devise general models of nonmaximizing behavior, so that bounded rationality assumptions often maintained an ad hoc, hardly generalizable character. Partly for this reason, the optimization model retained its prominence for long.

More recently, a current of thought known as 'behavioral economics' has provided abundant evidence against the individual optimization model. Starting from a seminal contribution (1979) by Amos Tversky (1937–96) and Daniel Kahnemann (born 1934), it has been shown that people make decisions based on simplified heuristics such as routines and habits rather than rigorous logic, and use mental emotional filters to respond to changing circumstances. In contrast to the microeconomic paradigm that aims at a value-neutral, highly abstract representation of decision making, behavioral economics reintegrates psychological elements into the analysis, explicitly investigates pro-social behavior, and compares and contrasts it with self-interest and selfishness – renewing, in a sense, with the older tradition initiated at the time of Adam Smith.

Regarding market models, after World War II it was the general equilibrium model that most attracted the attention of economic theorists, largely due to the introduction into

economics of highly advanced formal tools and of a new way of thinking about mathematics, based on topology, convex set theory, and fixed-point theorems (Weintraub, 2002). The new tools allowed for a sophisticated refinement of Walras's approach, named the Arrow–Debreu–McKenzie model after its main contributors. A major achievement in the 1950s was a formal proof of existence of equilibrium. The difficulty was that it was not enough to show that the system of simultaneous equations representing equality between supply and demand in all markets has a solution: For this solution to be meaningful economically, and not only mathematically, it was also necessary to prove that equilibrium prices and quantities are nonnegative. By demonstrating that it is indeed the case, it was established that the notion of a set of prices that clear all markets is consistent (i.e., the notion of equilibrium of a system of interrelated competitive markets is not void).

Another success for general equilibrium theory was the mathematical proof of the so-called two theorems of welfare economics – a modern reinterpretation of Smith's 'invisible hand.' The first theorem states that a general equilibrium corresponds to a socially optimal allocation of resources, and the second states that, under some conditions, any socially optimal allocation of resources can be sustainable by a general equilibrium. These results amounted to rigorously establishing the desirable properties of the free market mechanism that earlier economists like Adam Smith had put forward only intuitively or metaphorically. In sum, the new approach completely transformed general equilibrium theory, allowing to make it "rigorous, to generalize it, to simplify it, and to extend it in new directions" (Debreu, 1984: p. 267).

In the 1950s and 1960s, such progresses put the Arrow–Debreu–McKenzie model at the center of the stage and increased confidence in its potential to provide the whole of economics with rigorous mathematical foundations. However, problems started with attempts at proving two other key properties of equilibrium – namely, stability and uniqueness. The question of stability was meant to ensure that after an exogenous shock, the market mechanism is capable of generating endogenous forces that bring it back to equilibrium; if equilibrium exists but the market cannot find it, then arguments for free markets are harder to make. In addition, if uniqueness is not guaranteed, it is unclear where an adjustment process might drive the system after a shock; besides, some equilibriums may be unstable. It became soon clear, though, that formal proofs of stability and uniqueness could be obtained only under excessively restrictive, unrealistic assumptions. Critics stressed that these results reveal that with all its mathematical underpinnings, general equilibrium theory did not truly succeed in improving knowledge of how the market mechanism works and how prices adjust in response to variations of supply-and-demand conditions (Kirman, 1989; Ingrao and Israel, 1990). Despite these shortcomings, general equilibrium theory remained central for long, and is still in the core of economists' education; the publication in 1995 of a celebrated graduate textbook by Mas-Colell et al. (1995) condensed and systematized the essence of the knowledge available at the highest level.

At this point, the consolidation of the microeconomic paradigm founded on constrained optimization of the individual economic agent and the general equilibrium of all markets appeared as a monolithic bloc – a standard, more and more firmly established 'mainstream' allowing less and less different perspectives. The micro-foundations movement, in its effort to integrate core microeconomic principles into macro, seemed to further reinforce the mainstream's primacy. Microeconomics seemed at the same time successful, and stagnating, unable to move any further.

Yet a closer look reveals that the evolution of microeconomics in the decades that followed World War II was more diverse than may seem at first sight. Alternative and heterodox economic theories, explicitly challenging neoclassical microeconomics, have never ceased to exist even though their place, relevance, and visibility seemed to somehow shrink over time. A complete review of their approaches is beyond the scope of this article; But it is worth briefly mentioning two key developments which, initially not among the most vocally critical of the state of microeconomics, have been highly successful and over time, have progressively grown to be integrated into the mainstream as it is today. First, the general-equilibrium image of individuals making decisions in isolation from one another, letting an impersonal market mechanism establish the prices that will guide their decisions, progressively gave way to a more active view of decisions as strategic reactions to other agents' own actions. In contexts in which interdependencies are strong, such as imperfectly competitive markets, economic agents anticipate the direct repercussions of their choices on others, and of others' choices on themselves. Game theory has proven to be the appropriate technique to explore the structure of strategic interactions and the direct effects of individual decisions on one another. Initiated in the 1940s with, among others, a seminal contribution of Oskar Morgenstern and John von Neumann (1944), game theory experienced a rapid development and an extraordinary expansion of its application to economics since the 1980s.

Second, Marshall's partial equilibrium remained in the shadow for a while, largely due to a devastating critique from Piero Sraffa (1925) who questioned its logical consistency; But it did not entirely disappear. The static supply-and-demand diagram was used in some applied studies, while the dynamic conception of sequential transactions between pairs of buyers and sellers, underdeveloped in Marshall's own time, was refined with the help of novel, nonmathematical techniques. It underpinned the pioneering laboratory experiments on markets that were implemented by Edward Chamberlin (1948) and Nobel Prize Vernon L. Smith (1962). Although experimental research remained a tiny niche within economics for long, it kept alive the Marshallian approach, in its dynamic connotation. Partial equilibrium experimental markets gained renewed interest in the 1990s, and the properties of the exchange dynamics that they generate are sometimes referred to in the literature as 'Marshallian dynamics' (Friedman and Rust, 1993).

Interestingly, the first experimental markets inspired by Marshall's dynamic orientation were being devised at the same time in which set-theoretical mathematical techniques were being implemented to model Walrasian systems. These tools were rudimentary at the beginning (Chamberlin simply relied on his students and a blackboard to perform his market experiment), but they became more sophisticated over time with the increased availability of software for computer-based

experiments, and are thriving today. They embody a view of economics that gives less weight to the logical rigor of formalization than to the theory's fit with empirical data, assessed with objective, well-defined, and replicable (laboratory-based) measures.

State of the Art and Future Perspectives

The mainstream edifice of neoclassical microeconomics erected throughout the twentieth century is still largely in place, and is still the basis of most economics teaching; yet its scientific underpinnings have undergone a process of profound rethinking and revision. Both general equilibrium analysis and the individual optimization paradigm have come under fire from critics of diverse obedience, including (but not limited to) behavioral economists. Research in general equilibrium theory now experiences a slow but neat decline; and studies of the principles of individual decision making tend to follow the behavioral rather than the neoclassical approach.

Yet far from languishing, the field is renewing itself at an unprecedented pace. The current tendency is to increasing diversification of approaches, methods, and topics, seemingly reversing the trend toward unification of the different parts of microeconomics observed in the twentieth century. Against the decline of – once dominant–general equilibrium theory, partial-equilibrium and experimental approaches are on the rise, and game theory has become the essential mathematical structure and support of a broad range of economic analysis. A case in point is market design – the study of how to define, enforce, and monitor trading rules that maximize the efficiency of exchange, for example in auctions. Part of the motivation for these studies in the 1990s and early 2000s was the need to design trading mechanisms that would help governments to privatize companies or state infrastructures, or to allocate property rights – the 3G auction in the United Kingdom being regarded as one of the most successful examples (Binmore and Klemperer, 2002). The design of an auction for the Bank of England's liquidity insurance operations is another case in point (Klemperer, 2010). These studies depart from the general equilibrium tradition by, first, using insight from game theory to highlight the importance of trading institutions to yield socially desirable outcomes, instead of abstracting them away; and second, by concentrating on single markets rather than global interdependencies – Marshall's 'partial equilibrium' perspective.

Partial equilibrium approaches also underlie a growing body of research on Internet markets, especially with the study of so-called 'two-sided' markets. This expression designates markets in which two different sets of agents interact through an intermediary or platform, and the decisions of each set of agents affect the outcomes of the other set of agents, typically through an externality (Rysman, 2009). Internet and media companies operating between advertisers and consumers are a typical example, along with the payment card industry (between merchants and customers). Pricing is usually asymmetric, and depends on the price sensitivity – the elasticity of demand – of each side; it often turns out that one side does not pay, or is even rewarded for using a service (with cash-back for credit card use for example), while the other, more price-inelastic side faces a high mark-up (Rochet and Tirole, 2003, 2006). Research in this area is booming and top microeconomic theorists are increasingly often consulted by, or serve as chief economists of, major Internet companies.

These examples bring to light a second major tendency in today's renewal, that for microeconomics to become much more practically oriented and empirically informed. If nineteenth- and twentieth-century microeconomics left aside quantification to adopt formalization (an approach that purports to develop hypotheses and explanatory arguments independently of, or prior to, confrontation with empirical data), recent research uses empirical investigation methods to test theories against data, thereby typifying a third and more recent use of mathematics, namely *validation* and verification, testing (formal) theory against (quantitative) data according to some version of the scientific method. To do so, new sources of information are being exploited, notably experimentation and analysis of survey and administrative data with the help of increasingly sophisticated microeconometric techniques. These techniques are now recognized parts of the field and attract an increasing number of young economists.

The future of microeconomics is, in sum, still open, with promising developments in several subfields and still greater potential for further success, and with access to an ever-wider and more diverse set of tools, techniques, theories, and datasets. Yet the precise directions of its future developments are still unclear – many paths can be taken, and the major task of choosing which ones to take lies ahead of microeconomists in the near future.

Abstract

Biological changes that occur along time or space within a species are called microevolutionary. The basic factors responsible for them are (a) mutation (changes in the genetic material) and (b) natural selection (the preservation of favorable and elimination of deleterious mutations). Other factors, however, may influence this process. They can be categorized as population size (in small groups, random processes may be important), interpopulation migration (number and type of founders), and assortative mating. In humans, culture can decisively influence these and other parameters; and concerns are raised over recent opposition to the use of DNA in human population studies.

Concept

The word 'evolution' derives from the Latin term *evolutio*, which means 'an unrolling.' It can be used in this sense, or in others that involve the idea of change. But not all changes are evolutionary. The ocean's surface is always changing, but this is not an evolutionary process. Implicit in the concept of evolution are (1) continued change, (2) divergence, (3) restriction of opportunities, and (4) in a large number of situations, irreversibility. It is questionable whether there is a general direction (hence, 'progress') in the organic evolutionary process.

The primary factors that determine evolution are mutation (genetic change) and selection (in Charles Darwin's words, "The preservation of favorable individual differences and variations, and the destruction of those which are injurious" (Darwin, 1859)). The two, however, can be influenced by population structure. Among the variables that should be considered in this latter context, mention should be made of population size, the mobility and life histories of its members, sex and the genetic system, and assortative mating.

The dazzling array of organic diversity present on earth has always fascinated humankind. An important property of this variability is that it is discontinuous. Organic matter is organized in discrete individuals and groups of individuals. Moreover, these groups may be isolated reproductively from other similar ensembles. When this occurs, it is said that they are different species.

Microevolutionary processes are those that occur within a species. *Homo sapiens* is a particularly favorable subject for the investigation of these processes because, of course, humans know much more about themselves than about any other organism. However, humans are unique among other forms of life because they developed culture to an unprecedented degree. This trait varies according to its own laws, and is largely independent of biological factors. The reciprocal, however, is not true; organic evolution in humans may be strongly influenced by cultural processes.

Mutation

The information needed to assure the transmission of biological inheritance is given by a molecule, deoxyribonucleic acid (DNA). The particular sequence of its component units (nucleotides) is important because it codes (through another molecule, ribonucleic acid (RNA)) for the sequences of amino acids, the protein units that, when combined in arrays, make up physical bodies. The unit of heredity is the gene (present in a locus), composed of coding exons and noncoding introns (which probably have regulatory functions, e.g., they may modulate exonic gene expression). The transmission takes place in DNA–protein arrays called chromosomes. The genetic material can occur either in the nucleus of the cells or in the cytoplasm, in an organelle called the mitochondrion.

Detrimental agents or problems during the replication process may lead to mutations, changes in the previously existent DNA sequence. Advances in the molecular study of these structures revealed that many different types of change may occur, such as alteration in just one nucleotide, deletions or insertions of many of them, triplet (the coding unit is made of trios) expansions, variations in nucleotide position, changes in the process of DNA → RNA → protein information transfer, unequal recombination, and gene conversion between different DNA strands. Moreover, these variations do not occur at random. There are changes that are allowed and others that are forbidden, depending on the importance of the particular DNA region for cell physiology. Their fate will also be quite different if they occur in noncoding or coding regions. A special type of change is that which occurs due to horizontal DNA transfer, that is, pieces of DNA (transposons) move from one species to the other, or between chromosome regions of the same species, helped by infectious agents.

Although the human per-generation mutation rate is exceptionally high, on a per-cell division basis the human germline mutation rate is lower than that recorded for any other species. Aspects of our specific gene structure condition the production of defective alleles, and our longevity leads to an accumulation of somatic mutations. Therefore, Lynch (2010) predicted a substantial reduction in human adaptation in the coming centuries in industrialized societies, where mutagenic agents (physical, chemical, or biological factors causing alteration in DNA molecules) are more prevalent.

A kind of variation that only now can be assessed in a quantitative way is copy number variations (CNVs), which are variable adjacent arrays of repeats, deletions, and duplications. Conrad et al. (2010) mapped 11 700 CNVs in 450

individuals of European, African, or East Asian ancestry. This information will significantly enhance our ability to identify sources of pathological agents in our species.

Natural Selection

Natural selection is, like mutation, a category that involves many different processes. For instance, selection may be directional when it changes the adaptive norm of a population; stabilizing when this norm is protected; or balancing, which includes all those factors that maintain genetic heterogeneity or polymorphisms (common variants). Selection occurs at all levels of the biological hierarchy (molecular, cellular, tissue, organ, individual, population, species, and community of different taxonomic entities), and its agents are accordingly diverse (Salzano, 1975; Williams, 1992).

A current sustained effort to identify selection in humans is through molecular analysis of common variants (polymorphisms), which are compared with different aspects of our physical and socioeconomic environment. In this context, the selective sweep model was developed. Two situations can be envisaged, labeled as hard and soft sweeps. In the first case, a new, strongly beneficial mutation increases in frequency until fixated in the population. Due to the fast rate of the process, there is little opportunity for recombination to separate the variant from its genetic background, leading to a sweep (reduction) of neutral variation at linked sites. This event distorts allele frequencies at these regions and affects patterns of linkage disequilibrium (departures from free recombination along regions of a given chromosome). In soft sweep, selection would act on preexisting genetic variation that was previously neutral or deleterious, but became adaptive due to changes on the environment or genetic background.

There are ways to identify both phenomena through molecular analysis, and Hernandez et al. (2011), using sequencing data from 179 human genomes, concluded that hard sweeps (the results of a single instance of mutation spreading through the entire population) were probably rare in our evolutionary past 250 000 years. This finding does not imply that positive (based on advantageous alleles) selection was not important for human evolution. Akey (2009) surveyed 21 genome-wide scans for recent or ongoing positive selection in our genetic material, highlighting their main aspects. Stearns et al. (2010) also reviewed how selection could be measured in contemporary human populations, giving specific examples.

How can selective pressures be measured? Hancock et al. (2011) correlated allele frequencies and climate across 61 worldwide populations. The most extreme signals of selection were associated with pigmentation and autoimmune diseases. Tennessen and Akey (2011), however, found that selection has favored modest divergence at particular loci multiple times in independent human populations. Another approach focused on pathogen-induced selection pressures, considered by Fumagalli et al. (2011) and Novembre and Han (2012).

The *paired box homeotic gene 9*, a transcription gene with a major role in early development, including dentition, shows a peculiar evolutionary trend. It has four exons; the first acts uniquely as a start codon, exons 2 and 4 are evolutionarily highly conserved, but exon 3 has a high level of intraspecific variation, and one of its alleles (*Ala240Pro*) is associated with the third molar agenesis, a trait that could be advantageous in populations with progressive reduction of the dental arches, which could be due to diets based on processed food. The reduction would prevent impacted and defective third molars, as well as related oral problems, an important cause of morbidity in nonindustrial societies (Paixão-Côrtes et al., 2011).

Population Structure

Selection can act through differences in mortality or fertility, and a dialectic dilemma that faces any organism is how much energy it should invest in individual survival, as opposed to reproductive efforts. Throughout human history, significant changes have occurred in the emphasis given to these two processes, and they have been connected with subsistence patterns greatly influenced by culture. Among hunters and gatherers, mobility was very important, and the nomadic way of life would disfavor large numbers of offspring. Several measures were then developed to assure a small number of children (herbal contraceptives, mating taboos, abortion induction by mechanical means, and infanticide). Variance in number of children, a key evolutionary parameter, was thus restricted. Since population numbers were small, infectious agents would not be very important, and mortality would be mainly determined by other environmental factors or by violent deaths determined by rival groups.

The situation changed with the domestication of plants and animals. The premium now was to have a large number of children, to help in the cultivation and harvest of plants, or to take care of the animals. The possibility of storing large quantities of food made life more independent of the environment, and there was a concomitant increase in population size. Higher mortality levels then developed, due to epidemics and also due to the fact that it is easier to take care of two as compared to, say, 10 children.

Modern technology made possible a better control of number of children and of infectious agents. The action of natural selection, therefore, became more restricted.

Tribal groups have a population structure largely determined by what Neel and Salzano (1967) proposed as the fission–fusion model. Fissions can occur due to social tensions, the migrating units being composed of lineal relatives; and fusions, as convenience dictates. Using more than 580 000 single-nucleotide polymorphisms (SNPs), Henn et al. (2011) studied three hunter-gatherer African populations and compared a subset of 55 000 of these SNPs with those of 24 other groups of the same continent. Hunter-gatherers have the lowest level of linkage disequilibrium among the set, but continue to maintain the highest levels of genetic diversity found in the world.

Arylamine N-acetyltransferase 2 (NAT2) is a protein involved in physiological responses to a variety of compounds, including common therapeutic drugs and exogenous chemicals present in the diet and the environment. Sabbagh et al. (2011) collected information on 128 population samples (in a total of 14 679 individuals) representing different subsistence modes and dietary habits. A significantly higher prevalence of the slow

acetylation phenotype was found in populations practicing farming and herding than in those relying on hunting and gathering. The Neolithic transition, therefore, should have modified the selective regime affecting the NAT2 acetylation pathway.

Migration

Why do people migrate? Certainly, a series of socioeconomic and biological factors are involved in this process. Tovo-Rodrigues et al. (2010) investigated one of them, related to the dopamine receptor D4 system. Its gene (*DRD4*) is one of the most variable in the human genome, and the *7R* allele is associated with a novelty-seeking personality dimension, impulsivity and hyperactivity. Tovo-Rodrigues et al. (2010) compared the *DRD4* allele distribution in 23 Native American populations and found that *7R* is significantly more frequent in hunter-gatherers as compared to agriculturalists. Their explanation for this finding is that exploratory behaviors would be adaptive in nomad societies, because they allowed for more successful exploitation of resources. Conversely, in agriculturalist sedentary societies, novelty-seeking and exploratory behaviors would have social costs, because these populations developed intensive methods for using the land in a given settled environment.

At the macrodistribution, continental level, it has been proposed that the east–west orientation of the Eurasian landmass facilitated the rapid spread of ancient technological innovations across it, while the north–south orientation of the Americas would have led to a slower diffusion of technology there (Diamond, 1997). If the diffusion of technology was accompanied by gene flow, then genetic differentiation in the Americas along lines of longitude would be greater than that in Eurasia along lines of latitude.

Ramachandran and Rosenberg (2011) employed 678 microsatellite loci (composed of different adjacent duplications) from 68 indigenous populations of both regions to examine this point. They found that genetic differentiation in the Americas occurs along both latitudinal and longitudinal axes, and has a greater magnitude than corresponding differentiation in Eurasia. If diversity is inversely correlated to gene flow, these results support the hypothesis of a primary influence for continental axes of orientation in the demic diffusion of technology in Eurasia and the Americas.

Assortative Mating

Mating choice is a complex behavior characteristic that involves psychological, cultural, socioeconomic, and biological variables. Its main evolutionary influence is on the distribution of genotype frequencies. In multiethnic communities, there is a clear preference for homogamic matings (mating with a partner from the same population). Recently, with the use of exclusively matrilineal (mitochondrial DNA) or patrilineal (Y chromosome) genetic markers, it is possible to evaluate the influence of sex when heterogamic unions occur, in historical perspective. Thus, in Latin Americans of mixed ancestry, the European component was mainly contributed by males, while the Amerindian fraction is mostly derived from females. This is a reflection of unions that occurred in the Colonial period and that could be detected independently of the demographic, cultural, and biological changes that occurred afterward (Salzano and Bortolini, 2002).

Our research group has been studying the Xavante Amerindians of Central Brazil for the past half of a century (see, e.g., Coimbra et al., 2002), and since the beginning observed that their morphology differed from those of other Amerindian tribes. Hünemeier et al. (2012a) subjected this observation to a detailed analysis, considering cephalometric data obtained from 1203 individuals, a sample that included five other Brazilian tribes (Baniwa, Kaingang, Kayapo, Ticuna, and Yanomama), plus a Mexican one (Otomí) used as an external group. This information was compared to genetic, climatic, social, and life-history data, which were submitted to complex mathematical–statistical analysis. The main finding is that the Xavante had a remarkable pace of morphological change, which was 3.8 times higher in relation to the average, and which included the geographically and linguistically distant Otomí. The differences found cannot be attributed to other genetic (mitochondrial DNA) or climatic factors, but sexual selection could be a culture-driven force worth considering. The reproductive success of some Xavante chiefs in their polygamous society was well documented, and the Xavante clearly depart from the Kaingang, Kayapo, and non-Amerindian groups in terms of marital correlation of anthropometric traits (Stark et al., 1990).

Culture

Two branches of mathematical evolutionary analysis are the gene–culture coevolutionary theory and niche construction theory. Description of the first approach was provided by Laland et al. (2010), who also presented a list of 129 genes whose rapid rate of change could have been attributed, at least partially, to cultural factors such as plant domestication, dairy farming, sexual selection, complex cognition, and diet.

Lactase persistence in adulthood is a classic example of such type of interaction, the causative mutations in the *LCT* gene and its enhancer region having increased in frequency in populations that relied on milk for their diets. Friedrich et al. (2012) have studied these genetic regions in 316 individuals from four Brazilian Amerindian populations. Only the *−13910*T* allele, responsible for the persistence of lactase in Europeans, was present in frequencies that varied from 0.5% to 7.6%. The near-absence of the variability on the enhancer region, however, was not accompanied by that on the coding portion of the gene, which showed different combinations of gene arrangements (haplotypes) with a heterogeneous inter-population distribution. Different evolutionary factors can be at play even in relatively close DNA segments.

Niche construction theory emphasizes the capacity of organisms to modify their environment and thereby influence their own and other species' evolution. Kendal et al. (2011) presented the fundamental principles of this concept, evaluated their consequences, and suggested how the human biological and social sciences could be integrated to provide specific examples of it.

The ATP-binding cassette transporter A1 gene variant (*ABCA1*Arg230Cys*), up to now found only in Native Americans or in populations partially derived from them, was associated with a cholesterol efflux reduction and could have been advantageous in the past during food deprivation periods. But under the current modern lifestyle, with its excess of food availability, it could have a detrimental effect, causing obesity and type 2 diabetes in its carriers (Acuña-Alonzo et al., 2010). This is, therefore, an additional example of the 'thrifty' genotype hypothesis, formulated by Neel (1962). Results of our group (Hünemeier et al., 2012b) showed a strong correlation (90%) between the radiocarbon dates of maize pollen relics found in archeological sites of Mesoamerica with the frequency of this allele in populations situated nearby. The evolutionary hypothesis established in view of these and other findings is that Mesoamericans constructed an ecological niche that relied mostly on maize cultivation, leading to conditions that were favorable to this specific gene variant (since dependence on just one crop would lead to frequent famine episodes).

Problems

Practitioners of bioethics, a term created by Van Rensselaer Potter in 1970, have been considering a series of problems, one of them being the ethics of biomedical research in human populations, particularly that involving tribal groups. Salzano and Hurtado (2004) considered in detail these latter aspects. Two important principles were postulated: (a) the well-being of the study population should be the researcher's top priority; and (b) full informed consent should be required. In addition, any economic profit eventually obtained from the study should be shared by the communities who provided the data.

It is unfortunate, however, that activists developed a pronounced hostility in relation to population genetics studies in these populations. Two examples illustrating this point will be given. First, in the Guidelines for Health Research Involving Aboriginal People issued by the Canadian Institutes of Health Research, article 14 states, "An Aboriginal community should have an opportunity to participate in the interpretation of data and the review of conclusions drawn from the research to ensure accuracy and cultural sensitivity of interpretation before submission for publication" (McInnes, 2011). There is no indication of who would judge the findings and the arguments that would instruct this judgment, or if just one vote would block the publication.

The second example is a paper by Reardon and TallBear (2012), who argued that all DNA research is carried out primarily by whites (therefore, ignoring the excellent investigations of, e.g., our Japanese and Chinese colleagues), and that researchers doing genomic science consider the DNA collected as their property. They also charged population geneticists of concealed racism. But they do not define what they consider to be 'white,' therefore, adopting the same racial typological thinking that they were trying to condemn! Of course, other social scientists do not share the same views. What is needed is a continued dialogue between researchers and research participants from diverse academic disciplines and ethnic backgrounds.

Human population genetics seeks to understand the history of humankind, not the history of specific groups. To restrict such research on the basis of the assumption that the rights or interests of certain groups are infringed by this research, without individual research participants making this point themselves, is an ethically very problematic strategy.

Abstract

Demographic microsimulation is an individual-based and computationally intensive tool used by population scientists to model demographic processes, to gain insights on life course transitions and to make projections. Several microsimulators have been developed, since the 1960s, to address questions for which standard techniques or data sets cannot provide answers. Examples of applications include historical studies of demographic constraints on household formation, the impact of the HIV/AIDS epidemic on kinship resources for orphans and the elderly, and the study of interaction and feedback mechanisms in demographic behavior. From the methodological point of view, calibration of stochastic microsimulators is an area of active research.

Demographic microsimulation is a computationally intensive tool used by population scientists to model demographic processes, to gain insights on life course transitions and to make projections. Two important features distinguish microsimulation from other models. First, the unit of analysis is the individual (hence 'micro'). Second, the sequences of events that individuals experience over time are the result of stochastic experiments with predetermined probabilistic rules. Transitions between states are typically generated using computer algorithms and techniques also known as Monte Carlo methods (hence 'simulation').

In a standard situation, each individual in the simulation is an observation in a rectangular data file, which contains records of demographic characteristics and other key variables of interest. The simulator takes as input population files and demographic rates, and updates the population accordingly. Each simulated person is subject to a set of rates, conditional on certain demographic characteristics such as age, sex, marital status, etc. For every predefined time interval, each individual faces the risk of a number of events including death, marriage, childbirth, and migration. The selection of the event and the waiting time until the event occurs are determined stochastically, often using a competing risk model. Some constraints may be included in the simulation program in order to restrict the range of potential events for particular subgroups of the population (e.g., to avoid social taboos such as incest, to allow for a minimum interval of time between births from the same mother, etc.). Each event for which the individual is at risk is often modeled as a piecewise exponential distribution. The waiting time until each event occurs is randomly generated according to the input demographic rates. The individual's next event is the one with the shortest waiting time.

Major Modeling Options

A number of microsimulators have been developed over the course of several decades to address different types of research questions. Microsimulation models can be classified into various categories based on some distinctive features.

Continuous versus Discrete Time

The scheduling of events for simulated individuals is an important feature of each microsimulator. The algorithms that determine the next event for each agent may treat time as a continuous or as a discrete variable.

In continuous-time microsimulations, the timing and sequence of events that individuals experience over the life course are the result of a competing risk model. For every event for which an individual is potentially at risk, the simulator randomly generates a waiting time until the event occurs. The most common waiting time distribution is the piecewise exponential. Other standard distributions include the Weibull and the Gompertz distributions (Willekens, 2009). The parameters for the distributions of waiting times are chosen according to the input demographic rates for each subgroup in the population. The individual's next event is the one with the shortest waiting time. Every individual is always at risk of death; only women in reproductive age are at risk of giving birth; only married people are at risk of divorce, etc. The relative risk of each event happening next depends on input demographic rates, which typically vary by age, sex, marital status, parity, etc. Once the scheduled event occurs, a new set of waiting times is generated and a new event is scheduled accordingly.

In discrete-time simulations, time intervals are modeled, instead of the exact times before events occur. Each time period is considered separately from the others and each event is executed only once within the time period. Different events may occur within the same interval of time. As time periods get shorter and shorter, results from discrete-time simulations get more and more similar to the ones of continuous models. Continuous models have some logical and practical advantages. In continuous microsimulations, it is the sequence of events and transitions that is modeled and not state occupancies at different points in time. In discrete-time models, the duration of events can be modeled only approximately. Thus, multiple transitions within a period of time require assumptions about the ordering and the timing of events. Moreover, discrete-time models cannot handle complex and interdependent sequences of events (Willekens, 2009).

Closed versus Open Population

Microsimulations where individuals can enter the sample only through 'birth' from an existing woman, and can exit only through 'death,' are referred to as *closed* models. Whenever new people in the simulated population are generated other than through birth, then the simulation is defined *open*.

The distinction between closed and open populations mainly refers to the modeling technique used to match partners. In closed-population models, the choice of the spouse is restricted to individuals existing in the population. In open-population models, partners with suitable demographic characteristics are created in order to satisfy the demand for spouses at any given time.

Closed-population models require complex matching algorithms and fairly large population sizes in order for the marriage market to clear. Open-population models do not require sophisticated matching algorithms. However, the history of newly generated individuals is typically missing. One of the main advantages of closed models is that they allow kinship ties to be tracked over time.

A standard example of closed-population kinship simulator is SOCSIM, a computer software developed at UC Berkeley in the 1970s. The computer program uses a two-stage process to pair eligible males and females from within the simulated population. When the next-scheduled event for an individual is 'marriage,' then the person is placed in a pool of eligible members to form a union. If a member of the opposite sex with appropriate demographic characteristics is available in the pool, then the two individuals are paired. Otherwise, the person stays in the pool until an appropriate mate 'picks' him or her, based on a random process with probabilities dependent on demographic characteristics of the two potential spouses.

In closed-population simulations, migrations are often modeled by introducing a group of people, representative of the 'rest of the world,' who evolve independently of the population of interest. Migrants, or entire families of migrants, are drawn from the pool of people who represent the rest of the world.

Starting Population

The initial population for a simulation can come from a cross-sectional sample of the entire population, like the group of respondents to a sampling survey, or can be a synthetic population generated in a way that is consistent with the expected age structure and other relevant characteristics of the population under study.

When the initial starting population comes from a cross-sectional data set representative of the entire population, then individual life histories are simulated for the future. This approach is relatively simple and guarantees that the starting population has demographic characteristics consistent with the ones of the population under study. However, no information on the history of individuals before the starting point of the simulation is then available. Therefore, most kinship ties cannot be reconstructed. In addition, when the initial sample size comes from a survey, it may be relatively small and thus there could be high levels of stochasticity in the outputs of the simulation.

Often, the starting population is produced using a synthetic procedure. A population of a given size, composed of unrelated individuals, is randomly generated. Then the population is projected forward for a long period of time (say at least 100 years) using demographic rates that generate a population consistent with the population under study at the beginning of the simulation (in terms of age structure, age at marriage, age at childbirth, divorce rates, etc.). In the synthetic population, kinship ties have been tracked and can thus be projected for the future.

Top-Down versus Bottom-Up

Microsimulation models simulate demographic events for individuals in a way that is consistent with macro-demographic rates. One of the goals of microsimulation is to evaluate the consequences of demographic change for a number of quantities of interest. The methodology can be seen as a top-down approach. An alternative line of individual-based simulations, often referred to as agent-based models, pursues a bottom-up approach. Agent-based models simulate agents with built-in behavioral rules of action and interaction with other individuals and their environments. The main goal of agent-based models is to study the emergence of global patterns from simple behavioral rules of autonomous agents.

Standard microsimulation models tend to emphasize the modeling of macro-to-micro interactions, and are used to evaluate the impact of policy changes, long-term demographic trends, and demographic shocks, on various quantities of interest. Agent-based models focus on the micro-to-macro direction and are often used to test theories and to evaluate the emergence of complex phenomena.

Although standard microsimulation and agent-based models are built on different assumptions and used for different goals, in practice the boundaries between the two approaches are not clearly defined. Agent-based models often include some macro-demographic rates that serve as macro-controls for the dynamics of the simulated population. Microsimulation, on the other hand, includes important behavioral rules that regulate, for instance, preferences and interaction in the marriage market.

Calibration

In principle, perfect knowledge of demographic rates should lead to an unbiased reconstruction of population dynamics and kinship networks through demographic microsimulation. The only uncertainty associated to the simulated kinship structure would be related to the stochasticity of the microsimulation. In practice, knowledge of vital rates is far from being perfect. Kinship reconstruction and forecasting demand a level of detail for demographic rates that is often missing in available data sets. For instance, transition rates from one marital status to another are usually not readily available and estimates may not be very accurate. Fertility rates are usually not broken down by marital status or parity, especially in the developing world. In most cases, demographic rates that are used as input to the microsimulation need to be estimated from various data sources with different sampling errors. Even when reliable data

sources exist to compute demographic rates broken down by the categories of interest, the heterogeneity of the population's rates within the tabulated categories constrains the accuracy of the microsimulation (Wachter et al., 1997).

Traditionally, the problem of calibrating microsimulations has been addressed using ad hoc tuning. Input rates are adjusted on a trial and error basis in order for the output of the simulation to match key summary demographic measures obtained from a population census or sample surveys. The validity of the microsimulation has been tested by comparing kinship forecasts generated in the past with external standards provided by surveys with detailed information on numbers and ages of kin in the United States (Wachter et al., 1997).

In the past, the development of methods to calibrate microsimulations has been mainly constrained by the limitation of computer power. Traditional methods have relied heavily on minimizing the number of simulation runs. That was done, for instance, using expert judgment for adjusting the input demographic rates in a consistent and appropriate way. With increasing computer power, there has been more and more interest in the development of methods to calibrate simulation models. The Bayesian melding method (e.g., Raftery et al., 1995; Poole and Raftery, 2000), in particular, has proved useful to formalize the process of calibration and statistical inference. It is a Bayesian approach since it relies on the Bayesian machinery of combining prior distributions with likelihoods to obtain posterior distributions. It has been named 'melding' because it "provides a way of combining different kinds of information (qualitative or quantitative, fragmentary or extensive, based on expert knowledge or on data) about different quantities, as long as the quantities to which they relate can be linked using a deterministic model" (Poole and Raftery, 2000). Sevcikova et al. (2007) and Zagheni (2010) extended the approach to stochastic simulations.

When using the Bayesian melding method, the researcher first has to express the available information about inputs and outputs in terms of probability distributions. For instance, this can be done by providing a prior distribution on the inputs. Then the researcher has to specify a conditional probability distribution of the data given the outputs. This yields a likelihood for the outputs, and, implicitly, produces a likelihood for the inputs. The combination of the prior on the inputs and the likelihood, using the Bayes' rule, gives the posterior distribution. In order to obtain the posterior distribution for the quantities of interest, Sevcikova et al. (2007) suggested a computational approach that is based on the sampling importance resampling algorithm of Rubin (1987, 1988). They applied the method to urban simulations. A similar approach has been used for the calibration of demographic microsimulations (Zagheni, 2010).

Some Applications

The idea behind the development of microsimulation methods as a research tool dates back to the late 1950s and early 1960s (Orcutt, 1957; Orcutt et al., 1961). Since then, a large number of microsimulators have been proposed and used to address demographic questions (Morand et al., 2010). It is beyond the purposes of this article to provide an exhaustive list of microsimulators and applications. Some illustrative examples that give a flavor of the scope of applications of microsimulation to demographic research will be presented in this section.

The study of kinship structure is one of the most successful applications of microsimulation models in demographic research. Two of the most widely used microsimulators are SOCSIM and CAMSIM. SOCSIM originates from a collaboration between Peter Laslett, Eugene Hammel, and Kenneth Wachter in the early 1970s. CAMSIM was developed in the late 1970s and early 1980s by Peter Laslett, James Smith, and Jim Oeppen (Zhao, 2006). Both simulators have been designed to study kinship networks. However, they use quite different algorithms, since SOCSIM is a closed model, whereas CAMSIM is an open-population simulator.

SOCSIM has been originally developed for historical studies of demographic constraints on household formation. In particular, it was used to test the hypothesis that social norms, and not unfavorable demographic conditions, were the cause of the low proportion of stem family households in pre-industrial England (Wachter et al., 1978). Other historical analyses include the assessment of the 1698 Slavonian census, using SOCSIM (Hammel and Wachter, 1996a,b) and the evaluation of potential biases in genealogical data, using CAMSIM (Zhao, 2001). A second line of research that has largely benefited from the use of microsimulators is the study of change of kinship availability over time. SOCSIM has been used to project kinship resources (including step-kin) for the elderly in the US (Wachter, 1997) as well as long-term changes in family and kinship networks in Britain (Murphy, 2011). Zhao (2006) offers a comparative review of applications of SOCISM and CAMSIM.

For countries with a generalized HIV/AIDS epidemic, microsimulation has been used to assess kinship resources for the elderly in Thailand (Wachter et al., 2002) and for orphans in Zimbabwe (Zagheni, 2011). Demographic microsimulations that include modules for the transmission and progression of HIV/AIDS have been used to model population dynamics of polygynous populations in sub-Saharan Africa (Clark, 2001). In the area of indirect estimation, microsimulation has proven useful to evaluate bias for methods developed to estimate mortality from sibling survival data (Masquelier, 2013).

Microsimulation has been the dominant research tool to analyze the consequences of demographic change for family and kinship networks. Agent-based models have recently emerged as a complementary tool to study marriage formation, choice of partners, and the role of behavior, interaction and feedback mechanisms in demographic research (Billari and Prskawetz, 2003). For instance, it has been found that relatively simple mate search rules that adjust on the basis of sequential encounters with potential partners may generate regularities in the distribution of the age at first marriage (Todd et al., 2005; Billari et al., 2007).

Strengths and Limitations

Microsimulation models have been developed to address questions for which standard tools could not provide an

answer. In that sense, microsimulation amplifies the power of scientific imagination of researchers, it allows population scientists to go beyond some of the simplifying assumptions made in standard macro-demographic models.

Microsimulation is the most appropriate tool when population heterogeneity and interaction matter, and when the number of variables and the number of attributes that these variables can take is very large (Van Imhoff and Post 1998; Spielauer, 2011). Microsimulation can accommodate interactions between individuals and between variables much better than macromodels with a large state space. More specifically, "microsimulation is particularly appropriate if the results of the process are complex but the driving forces of the process are simple" (Van Imhoff and Post 1998). Anytime processes are complex at the macrolevel, but better understood at the microlevel, or when individual histories are relevant, then microsimulation/individual-based models are the preferred choice.

Microsimulation is a very attractive tool both to gain insights into population dynamics and for policy-relevant analyses. However, there are two important limitations that need to be taken into account. First, microsimulations typically require high quality and very specific types of input data that are often not available. Moreover, even if detailed demographic data are available, the calibration process may prove difficult. Second, failing to model correlations between demographic events in models of kinship may lead to less variation in the frequency of kin of any particular type than would occur in the real population (Ruggles, 1993). In other words, models tend to underestimate the fraction of people with many kin and the fraction of people with few kin. In most situations the extent of the underestimation is very small and, for practical purposes, could be ignored. However, there may be cases where the size of the underestimation is not negligible and thus, in those situations, modeling of correlations is advisable.

Abstract

Situated between antiquity and Modernity, the Middle Ages constitute an intermediate period between the grand beginnings of European civilization and its contemporary achievements. An intermediate status is always ambivalent. Thinking in strictly dualistic terms, it is no longer the old and not yet the new, or, conversely, it allows the partial survival of the old and prepares the birth of the new. This article addresses three aspects: (1) the extension of European Middle Ages is both related to different periodization schemes of universal and national history, and situated in a geographical dimension. With the Roman Empire and Christianity as basic points of reference, this notion, born in Renaissance Italy and nurtured in Western Europe, has always embraced more than *Europa Occidens*. Besides a reconsideration of the North–South divide the specific medieval features of East-Central-Europe, the "borderlands of Western civilization" are described as well. For presenting these multiple and changing identities two methods are adopted: (2) the characterization of economic, social, and mental structures as debated by recent historiography, and (3) a historical chronology of narratives, personalities, and artifacts for adding life and color.

The Middle Ages are good to think. Situated by definition between Antiquity and Modernity, they constitute an intermediary period between the grand beginnings of European civilization and its contemporary achievements trying to come up to these standards and even surpass them. An intermediary status is always ambivalent. If one thinks in strictly dualistic terms, it is no more the old and not yet the new, or, conversely, it allows the partial survival of the old and it prepares the birth of the new. But it can also become an equally dignified participant in a triad: an age with special characteristics of its own. All this offers a paradise for conflicting interpretations, deprecations, and apologies; for an eternal to and fro of disdain, glorification, exoticism, and rediscovery.

The Notion of the Middle Ages

The most enduring characterization of the Middle Ages appeared already before the word itself was coined, it was inherited from Italian Humanists who had the habit since Petrarch to lament upon the 'dark' and 'barbarian' age between the glorious Greek and Latin Antiquity and the rebirth of this same quality in their own age. Yet, as soon as Renaissance was evolving into the new (post-Columbian, Gutenbergian, Copernican) world of Modernity, as soon as Middle Ages were regarded to be definitely over, condemnation got sided by waves of nostalgia: chivalric dreams resurrected by Ariosto, Cervantes, and Tasso, ideals of sainthood and a unified *Christianitas* cherished by the Catholic Reform, the Bollandists, Chateaubriand, and the Romantics. Medieval achievements like gothic cathedrals inspired both freemasonry and waves of occultism. The brutish energy of castles, armors haunted the imaginary with the Gothic Romance, but became also crystallization points for heroic-chivalric romantics, Wagner-type new barbarians, to degenerate finally into the comic world of Monty Python. The organic beauty of medieval cities and crafts was rediscovered by the Preraffaelites, by Burckhardt and Huizinga, the *art nouveau* and the *art deco*.

To these ambivalent judgments a third dimension must be added: that of different identities (local, institutional, national, and European). Medievalists inherited monastic annals, urban, or royal chronicles, order histories, and the history of western Christendom presented as world history. Much reasoning on Middle Ages was motivated, since Machiavelli's *Discorsi* (1525), Guicciardini's *Storia d'Italia* (1540), or Shakespeare's king-dramas by an interest of getting to know one's own 'national' roots. The antiquarian curiosity of Muratori (1672–1750) resulted in his path-breaking *Rerum Italicarum Scriptores*, the mighty and systematic source-collection on German past, the *Monumenta Germaniae Historica*, was started by Pertz (1826), the *Histoire de France* by Michelet (1833), the *Récits des temps mérovingiens* by Thierry (1840), or the studies on *The Constitutional History of England* by Maitland (1908). In the twentieth century historic attention also turned toward the universalistic frameworks: Christianity, Papacy, Empire, which could be analyzed as the 'birth' of Europe. Middle Ages meant the formation of modern Europe, which, based on its achievements, got ready for a world-wide expansion.

Then came the world wars and the revolutions and with them one could witness a new type of resurgence of interest in the Middle Ages. In front of destructive wars and equally destructive totalitarian states the safeguarding of the treasures of medieval Christian civilization became a task of universal importance. The appreciation of these values was helped by excellent studies in the history of religion, philosophy, fine arts, and literature, a host of new critical editions and a modern network of museums. Works by Auerbach, Delehaye, Haskins, Curtius, Gilson, Huizinga, Kristeller, and Panofsky have restored the dignity of the masterpieces of medieval thought and artistic creation, rooted in a value system and an aesthetic canon different from ours. Without all these medieval achievements the birth of renaissance, humanism, modern diplomacy, urban civilization, intelligentsia, and many other things would have been inconceivable. Even in the fights against the menace of modern barbarianisms one could usefully rely upon the legacy of the Middle Ages.

The simultaneously unfolding new interdisciplinary approaches, which tried to renew historical research, rediscovered a multicolored cultural variety that could be examined with an anthropologist's approach. The historians of the French *Annales* found a treasure-mine in the 'total' history of medieval civilization, and an unexpected series of best-sellers showed up: not only 'new history' monographs in the footsteps of *Montaillou* by Le Roy Ladurie (1985), but also new style historical romances as *A Distant Mirror* by Tuchman (1978) or *The Name of the Rose* by Eco (1980). From the 1980s on, châteaux, monasteries, city halls, but also modern university campuses became places for a permanent reinvention of the Middle Ages.

At the end of the twentieth century two further elements joined this picture. The collapse of Communism in Eastern Europe reoriented historical consciousness to medieval origins. Sometimes in a nineteenth-century style, as claim for territorial legitimacy, sometimes as foundation of the 'common roots' of their new European identity. The other novelty was provided by chronology. The year 2000 brought about a new fascination with the apocalypse, with some divergence in Eastern Europe: where instead of chiliastic calculations, pompous millennial celebrations were held remembering the glorious founding time of their Christian states.

Which Middle Ages should we address in the new Millennium, whose concept should we adopt? I will approach this from three angles: (1) periodization, (2) structures, and (3) a historical panorama of narratives, personalities, and artifacts.

Extension and Limits of the Middle Ages

As indicated, the concept of the Middle Ages was conceived by the Renaissance. The term *media tempestas* makes its appearance in 1469, in a praise of Cusanus by Bussi, a pontifical librarian. Analogous expressions (*media aetas*, *media antiquitas*), show up frequently and ally to the already established concept of 'dark ages' known from the writings of Petrarch, Bruni, Valla, and other Italian humanists.

But the notion of a transitory period between antiquity and its rebirth was older and this effects the chronological limits of the Middle Ages. Laments upon the lost greatness of ancient Rome and hopes of its imminent revival are already voiced by Gregory the Great. From Justinian I and Charlemagne to Otto III or Frederick Barbarossa, the slogan of *renovatio imperii Romani* repeatedly allowed the conceptualization of intermediary decadent periods. For the 'renaissance of the twelfth century,' perhaps the Arabic learning could be regarded as mediator between the wisdom of the *antiqui* and the Christian learning of the *moderni*.

The negative image of medieval decadence of classical civilization, however, was duly counterbalanced by the positive image of the advent of Christianity, the triumph of which upon Roman 'paganism' was praised as the demise of 'superstition,' 'tyranny,' 'idolatry,' and 'magic.' The judgment about the period following the fall of the Roman Empire was thus, rather positive during the Middle Ages, or at worst ambivalent. This is also reflected in the first elaborate system imposing a ternary division upon world history, that of Joachim of Fiore (+1202). Projecting the Holy Trinity model upon the history of mankind, Joachim distinguishes between the age of the Father (Old Testament), the age of the Son (New Testament), which lasts from Jesus to his own age (this actually corresponds to Middle Ages), and the imminent new period of the Holy Spirit, which will have an 'Eternal Evangile,' and where everybody would literally follow Christian life-precepts.

Early modern historiography inherits from the Renaissance the ambivalent image about the Middle Ages, and extends it to embrace universal history. Horn, a historian from Leiden, puts *medium aevum* between 300 and 1500 in his *Arca Noe* (1666). Cellarius, a historian from Halle, is the first to realize his world history on the basis of the ternary division into Antiquity (*Historia antiqua*, 1685), Modernity (*Historia nova*, 1986), and the Middle Ages between them (*Historia medii aevi*, 1688). The start of the *medium aevum* is for him the reign of Constantine and the acceptance of Christianity (313), and the end is marked by the fall of Constantinople (1453) (*see* Time, Chronology, and Periodization in History).

These limits were challenged by later suggestions. The 'start' was increasingly identified with the forced abdication, in 476, of Romulus Augustulus, the Western Roman Emperor, whose vacant throne never got filled again. The 'end' was rather brought in connection with the discovery of America (1492) or the start of the Reformation (1517). National histories adjusted dates to the dividing lines within their own field, English tend to count modernity from the advent of the Tudors (1485), Hungarians take the fatal defeat from the Ottomans at Mohács, in 1526, as end of medieval Hungarian history.

With an eye on Polish discourses on 'feudal economy' in the early modern times Le Goff made the provocative proposal of a 'long Middle Ages,' lasting till the French Revolution. Extension goes both ways: since the works on 'late antiquity' by Peter Brown, a five century long transitory period is replacing the divide of the 'fall' of Roman Empire, a period embracing the history of the Mediterranean basin from Diocletian until Charlemagne.

The extension of the Middle Ages has also a geographic dimension. With the Roman Empire and Christianity as basic points of reference, this notion, born in Italy and grown in Western Europe, has always embraced more than *Europa Occidens*.

The Mediterranean basin as a lively civilization-unit throughout the Middle Ages was a truism for the historians of commerce, crusades, or navigation. Yet, it had to be confirmed by Pirenne in his *Mohammed and Charlemagne* (1937b) and by Braudel in his *Mediterranean World* (1949). This rediscovery obliges historians of Latin Christianity to communicate with the large and autonomous tradition of Byzantine studies (Ostrogorski, Obolenski, Patlagean), and engage into systematic comparisons. Parallel to this renewed interest to an integrated panorama of the South, there was also a resurgence of nineteenth century visions on the 'barbaric,' individualistic vitality, and communal freedoms of the Germanic and Slavic North (*Markgenossenschaft*, *zadruga*). The medieval Roman and Germanic synthesis are also became the object of a new type of structural history by Pirenne (1933 [1937a]) and Bloch (1939). The medieval origins of Eastern, Central, East-Central, and South-Eastern Europe, these 'borderlands of Western civilization' have also been examined in impressive syntheses by the Romanian Iorga (1908–12), the Czech Dvornik (1949), the Polish Halecki (1952), or the Hungarian Szűcs (1990).

Structures in the Middle Ages

Defining a period within history requires the characterization of the structures that provide its identity and coherence; whether supposed to be 'objective,' deep structures, or the product of a momentary combination of various factors, or just an order observed by those who detect genealogies from a posterior moment.

The most general structural account imposed upon medieval period is that of 'feudalism' (*see* Feudalism), a notion which embraces social, economic, and cultural relations. Based on medieval legal concepts, '*féodalité*' served as the most general characterization of Ancien Régime during the Enlightenment (Montesquieu, Voltaire, Vico), was further developed by economic and sociological theory (Smith, Marx, Weber), to provide finally, with the work of Bloch, Duby and Le Goff, a comprehensive account of 'feudal society' and its economic structures, social stratification, habits, mentalities, rituals, cultural and religious achievements. Historical analysis found an attractive subject in this personalized power-structure which supplemented the early medieval weakness or lack of sovereign state. Sealed with the ritual of vassalage and with the conditional donation of a *feudum* (fief), 'feudalism' constituted a complex relationship of military, economic, social (and within it parental-familial) dependence and solidarity, one of the most original features of the Middle Ages, the foundation of Europe's future achievements, as it seemed.

Departing from a chaotic self-organization of early medieval times, evolving into the flowering of the 'second feudal age' (Bloch), feudal relations were analyzed along ecclesiastic, chivalric, courtly, and urban ramifications. The concept of feudalism also allowed the comparison of medieval Europe with other world civilizations, and Marxist historiography relied upon this when for coining a universal evolutionary pattern of world history. Renewed attempts discussed 'feudal economy,' 'feudal mutation' around the year 1000 (Poly and Bournazel), or regional European variants of feudal social structure. On the other hand, the exaggerated extension of this notion also led to an outright refusal of the concept (Brown, Reynolds).

Besides this synthetic vision of an all-encompassing pyramid of feudal dependencies other original medieval types of social structure should be mentioned. 'Orders,' appearing around the year 1000 as a horizontal classificatory category, referred to alliances of monasteries such as the Cluny *congregatio* or later the Cistercians, and they were also used for a general functional tripartition within society (*oratores-bellatores-laboratores*). This latter 'ideology' (Duby) prepared the late medieval appearance of 'estates' as social entities meriting political representation. Chivalric orders, religious confraternities, urban guilds, medieval universities lend this 'corporative' principle a crucial role within medieval society.

As a combination of contemporary distinctions and posterior classification, social classes, stratification and social types are frequently discussed. From the principal divides of ecclesiastical society and laity, nobility with its higher and lower strata, courtly and urban society with the respective microcosm of rank-related, social, institutional, religious, and ethnic distinctions among its permanent and temporary inhabitants, peasantry with various phases of unification or diversification of their status, the broad space of roads, forests, suburbs left for marginal existence where the poor, the outlaws, the pilgrims, the merchants, the hermits, the wandering knights could mingle. Within these social categories one can also observe elementary structures: family (with its gender and age divisions: changing status of women, children, and the old), 'parenthood' (understood as extended kinship-group) (*see* Family and Kinship, History of; Gender History), 'individual,' 'community,' '*gens*,' and '*natio*.'

Disruptions and transformations caused by invasions and internal wars should also be considered: attacks by, and eventually settlement of migrating tribal warrior societies (Goths, Francs, Lombards, Huns, Turcs, Avars, Vikings, Hungarians, Cumans), fights with the Arabs from the fall of Vizigothic state to the successful *Reconquista*. External menace not only disturbed but also unified: the consciousness of being '*europeenses*' emerged among Carolingians confronting the Arabic threat. Medieval Europe entered the phase of expansion with the Crusades and the evolution of long-distance trade, and the concept of European identity reappeared with the *timor Tartarorum* in the thirteenth and with the progress of the Ottoman occupation in the fourteenth and fifteenth centuries.

Throughout the Middle Ages, Europe possessed a general structure of universal bonds, which mingled with a variety of local and regional particularisms, and were in a continuous tension and conflict with them. Politically speaking, this universality was embodied in the Empire, or rather the two inheritors of the Roman Empire, the Carolingian and then Holy Roman Empire in the West and Byzantium in the East. These universal powers were confronted with a jungle of local, regional, institutional, communal and individual counterpowers. Resisting tribal retinues, territorial lordships supported by fortified castles, ecclesiastical immunities, urban liberties, noble privileges, constitutional rights, courtly intrigues, popular revolts, bloody wars paved the way to the emergence of 'national' kingdoms. The principle of *rex imperator in regno suo* finally subjugated both universal structures and local autonomies; the birth of the modern Europe of sovereign nation states was among the most significant outcomes of the Middle Ages (Strayer).

From the religious and cultural point of view the universal bond within medieval Europe equals *Christianitas*, based upon ecclesiastical structures (bishoprics, dioceses, parishes) of the Roman Papacy and the Eastern Churches with their three sacred languages. The history of medieval Christendom (*see* Religion, History of) brings a continuous expansion of internal and external conversion, defeating the resistance of the '*barbaricum*,' integrating local beliefs and cultural diversity, relying upon the omnipresent cult of saints increasingly controlled and standardized by Papacy (Vauchez, Klaniczay), the universal networks of monastic and mendicant orders, upon an emerging intellectual elite issued from medieval universities, imposing a unified pattern of literacy, Roman and Canon Law, scholastic theology, a kind of *philosophia perennis* (Gilson). Within such universal frameworks, historical evolution unfolded along the conflictuous lines of religious renewal movements (often labeled and repressed as heresies) and a series of renaissances (the Carolingian, Ottonian, twelfth century ones, and the Renaissance) which allowed an increasing absorption of Antique cultural heritage. Ongoing conflicts between 'learned' and 'popular,' Old and New Testament based, 'mystic,' 'liturgical,' 'rational,' and 'secularized' variants of Christianity

should also be mentioned. This could be studied in the universe of the cult of the saints, relics and miracle beliefs (Graus, Brown, Geary, Boesch Gajano Bartlett) or the in the prolonged conflict between 'popular religion,' archaic beliefs, 'superstitions,' heresies on the one hand and official dogma, its propagation (sermons, confession) and inquisition on the other (Bakhtin, Le Roy Ladurie, Ginzburg, Schmitt, Davis, Bériou, Elliott). Toward the end of the Middle Ages, universal frameworks could not contain the internal tensions any longer, and they succumbed, just like in politics, to the ascending nationalization of churches, legal systems, vernacular literature, and to the plurality of confessions within modern Europe, they gave way to an era of wars of religion, popular revolts, witch-hunts.

This enumeration of structures could continue with the 'hard' realities of geographic, climatic, ecological, demographic, and economic 'deep structures' (Braudel), with the 'soft' but equally enduring structures of '*mentalité*,' '*imaginaire*' (Le Goff) (*see* Psychohistory), with the 'thick description,' and the case studies of historical anthropology (Le Roy Ladurie, Ginzburg, Davis) (*see* History from Below, the History of Everyday Life, and Microhistory), with eternal dualities such as 'oral' and 'written' (Stock, Clanchy), 'body' and 'mind' (Bynum) (*see* Body, History of), with basic media such as 'text' and 'image' (Petrucci, Schmitt, Belting, Camille) (*see* Visual Turn), or with the intricacies and variabilities of old and 'new' philology (Cerquiglini). But this would require much more space, so let me rather conclude with a short and necessarily arbitrary overview of some concrete forms in which European Middle Ages live with us.

A Panorama of Narratives, Personalities, and Artifacts

The author of this article starts with grand destroyers of the 'old' (Roman, pagan Antiquity) and grand constructors of the 'new' (medieval Christian Europe). Constantine the Great (312–37) had both qualities: renouncing the divinity of the Roman Emperor, he preserved its sacrality in a Christian form, terminating the persecution of Christianity, he found a form of survival for classical culture, by shifting the center of his empire to the East, he contributed both to the thousand-year-long Byzantine continuation, and to the creation of the fertile dualism of Papacy and (an ever-renewing) Empire in the Latin West. Among the 'grand destroyers,' Attila, King of the Huns (434–53) merits precedence, his archetypal figure and his exploits became a model for all the oriental invaders till Dzenghis Khan. From among the 'grand constructors,' more should be mentioned. A model saint, turning from soldier to catechumen, hermit, monk and bishop: St. Martin of Tours (†397); two church fathers: St. John Chrysostome (337–407), Patriarch of Constantinople, and St. Augustine (354–430), Bishop of Hippo, path-breakers of personalized religiosity; an abbot, St. Benedict of Nursia, founding in 529 the model of Western monastic communities in Montecassino and writing the most influential Rule; an emperor, Justinian I (527–65), with his last attempt to restore and the first one to renovate the Roman Empire, his most enduring success was the codification of Roman Law; and finally a pope, Gregory the Great (590–604), organizer of medieval papacy, church hierarchy, liturgy, conversion.

In the dim light of early medieval legends, annals, and chronicles one perceives influential converters, as St. Patrick (390–461), the apostle of the Irish or St. Boniface (675–754), the apostle of Germany; churchmen making heroic efforts for salvaging classical culture, as Cassiodore (485–580), the Roman senator turned monk or Isidor of Sevilla (560–636) the Vizigoth bishop making a synthesis of antique learning in his *Etymologies*; impressive rulers, as the Frank Clovis (481–511), the Goth Theoderic (493–526), or the Northumbrian St. Oswald (634–42), powerful Merovingian queens as the wicked Fredegund, or the pious St. Radegund (520/5–87). The collective memory also preserves the narratives of the '*origines gentium*,' barbarian migration, conversion, and dynastic myths of emerging ruling houses (claiming divine origin). Following *Germania* of Tacitus, we hear thus of the Goths, the Franks (with the Merovingian dynasty), the Anglo-Saxons (with their Woden-sprung kings), and the Lombards (or later legends and stories related to the Scandinavian Yngling, the Slavic Přemysl, Piast and Rurik houses, the migrating Hungarians with their Arpadian dynasty).

A new chapter is starting with the Carolingians: the emergence of an influential family from the position of *majordomus* to royal and imperial dignity. Charles Martel stopping the Arabic invasion at Poitiers (732), Pepin the Short (741–68) and Charlemagne (768–814) making alliance with the Papacy remunerated by the imperial crown by Pope Leo III (800) – a symbolic moment in medieval history (McKitterick), which will find its counterpoint in 1077 in the Canossa – penance of Henry IV. The Carolingian renewal of state – church structures and social networks of dependence, the take-off in demographic, agrarian and urban growth, the 'renaissance' of high culture within closer courtly and monastic circles, the successful resistance against invasions (Avars, Arabs, Normans, Hungarians) – all this laid the foundations of a new triumphant evolution, unfolding in the West around the year 1000. There is a similar new start in the East with the Macedonian dynasty (867–1056), reorganizing the Byzantine Empire, successfully confronting Bulgarians, Hungarians, Russians, systematizing the army, the administration, and the ceremonies in the times of Leo VI and Constantine VII.

As for artifacts, while the splendor of Byzantium was incontestable, and radiated even in the remote mosaics of Ravenna and Venice, in the West early Middle Ages were not spectacular but essential: a massive diffusion of horseshoes, iron plow, water-mill, evolving naval technology of Vikings or Italian merchants. In culture new technologies of writing, such as the Carolingian minuscule book-illuminations, Gregorian chants, goldsmith works, evolving monastic and urban architecture, fortified castles indicate a new evolution.

Around the year 1000, one ruler stands out: the 'marvel of the world,' the Saxon Otto III, third emperor of the Holy Roman Empire (983–1002), allied to his French teacher Gerbert d'Aurillac, Pope Sylvester II (999–1003), and the Czech St. Adalbert (†997), the 'Apostle of the Slavs.' They coined a powerful new political vision for *Europa Occidens*, relating the integration of Germanic North and Mediterranean South to the extension of the influence of Latin Christianity toward Slavic and Hungarian East. Relying upon the earlier

conversion of Croats (Tomislav – 924) and the Czech lands of St. Venceslas (†929), now Poland of Bolesław the Brave (992–1025) and Hungary of St. Stephen (997–1038) also become parts of this 'new Europe,' which also extends toward the North. The Danes of Harald Blueteeth (940–85) and Sweyn Forkbeard (985–1014), the Norwegians of St. Olaf (1015–30) and later the Swedish get converted, with Anglo-Saxon and Germanic influence. This Christianization is conjugated with a parallel activity from Byzantium: on the paths of the previous ninth century Cyrillo-Methodian missions in Bulgaria and Moravia, in 996 Kievan Rus of St. Vladimir (980–1015) is converted.

Medieval Europe is profoundly renewed after the turn of the Millennium: new dynasties (Capetians, Salians, Normans in England and Sicily); reshaped religious life under the influence of Cluny; 'reform papacy' of Gregory VII (1073–85); Crusades proclaimed by Pope Urban II in 1095. Correlated with agricultural growth, population nearly doubles in two centuries, medieval towns multiply and acquire important immunities, liberties, a new dynamism unfolds.

Twelfth century brings the explosion of 'modernity,' of fertile tensions and conflicts, and of a wide array of grand figures. Abelard (1079–1142), the daring and unfortunate knight of dialectics, self-confident in his reliance upon reason, archetype of the medieval intellectual; St. Bernard of Clairvaux (1090–53), his opponent, the charismatic leading figure of the Cistercians, founding father of the Templars and organizer of the Second Crusade (1147–49), abbot, politician, healer, and mystic; Manuel I Komnenos (1143–80) Byzantine Emperor who tries to restore the ancient splendor of the East by starting a chivalrous rivalry with the crusading West; Arnold of Brescia (+1155), student of Abelard, apostolic preacher and tribune of a republican Rome that he hopes to resurrect, but hoping in vain the help of Frederick Barbarossa (1152–90), the great emperor from the Hohenstauf dynasty, who is rather for the *renovatio imperii* and gets him executed for his heresies; the martyr bishop St. Thomas Becket, who confronted his hard-willed youthful friend, Henry II Plantagenet (1154–89) and paid with his life for it in 1170. This is also a century of women: Heloise (*c.*1100–63), the seduced student, lover and wife of Abelard, who persisted in intellectual and emotional partnership after Abelard got castrated by her angry relatives; Eleanor of Aquitaine (1122–1204), grand-daughter of the first *troubadour*, Duke William IX of Aquitaine (1087–1127), herself also patron of poetry, wife of Louis VII, King of France (1137–80), then divorcing him in 1152 to marry Henry II Plantagenet, and take a third of France with herself as dowry; Hildegard of Bingen (1098–1179), the visionary nun of Rupertsberg, most prolific women-writer of the age.

Twelfth century is that of urban handicrafts, flowering fairs, schools, the beginning of the construction of cathedrals. It is also the century of crusades and knighthood under the banner of St. George, the 'dragon-killer,' Roland, King Arthur and the knights of the Round Table; it is the century of orthodox or heretic itinerant preachers from Peter the Hermit, summoning to crusade, Robert d'Arbrissel (†*c.*1117) stepping in for the emancipation of women, to Waldes, the rich Lyon merchant who distributed his wealth to the poor in 1173, and decided to live in mendicancy. When confronted with interdiction he accepted with his disciples, the Poor of Lyon, persecution rather than submission. Another heretic movement, the Cathars, were remote followers of the antique Manichaean dualists, more immediately related to the South-East European Bogomils.

At the beginning of the thirteenth century Christianity seemed suddenly to explode from conflicts: ongoing struggles between Empire, where Frederick II, the last great Hohenstauf (1212–50) was preparing for his *Ghibellin* exploits, and the Papacy which became a fearful rival with the *Guelph* dominated Italian towns on his side. Cities made international politics in the Mediterranean and in the North Sea: the Fourth Crusade was diverted by Venice to conquer Byzantium (1204), in the North the Hansa alliance, the future master of Scandinavian-Baltic region was growing. New problems arose within the cities: confraternities, 'people's parties,' lay preachers, rebellious students in Paris, Oxford and Bologna universities, or bank crashes in Florence and Siena. The fight against the heretics took the form of the crusade against 'Albigensians' (1209–29), which subjugated Southern France to the North; France being also in war with England and the Empire, with the victory by Philip August II (1180–1223) at Bouvines (1214). Noblemen were confronting their rulers to gain constitutional rights (Magna Carta – 1215; Hungarian Golden Bull – 1222). This burgeoning situation could be mastered with the help of two religious reformers, the founders of the two mendicant orders, St. Dominic (1170–1221) and St. Francis (1181–1226), and two popes, Innocent III (1198–1216) and Gregory IX (1227–41), who were capable of restructuring old resources and integrating new forces.

With the assistance of the Dominicans and the Franciscans the challenge of heresy could be confronted, the position of the Church got re-established in the cities where the pride of the emerging cathedrals and the accumulating new richness got balanced by the religious control of fashion, luxury, and usury and by charitable institutions of burghers moved by their '*alter Christus*,' the Poverello of Assisi. The Dominicans helped setting up the fearful Inquisition (1231) against the heretics and the popular 'superstitions,' in learning found balance between reason and faith, Aristotle and the Bible (St. Thomas Aquinas: *Summa Theologiae*, *c.*1267–73), and in princely courts Christianized rulership. The practical morality of their 'mirrors of princes' found echo in the ears of St. Louis IX of France (1226–70), most pious ruler ever, or his ambitious brother, Charles of Anjou, King of Naples and Sicily (1266–85), and many others. The religious message of the mendicant orders got also amplified by pious princesses: St. Hedwig of Silesia (1174/8–1243), St. Elizabeth of Thuringia (1207–31), Blanche of Castilia (1188–1252), St. Agnes of Bohemia (1205–82), St. Margaret of Hungary (1242–70); and daughters of Italian merchants, bankers, burghers: St. Claire of Assisi (1194–1253), Umiliana dei Cerchi (1219–46), Margaret of Cortona (1247–97) or Angela of Foligno (1248–1309).

By the end of the thirteenth century medieval Europe was prospering: after the successes of machine-supported cloth and textile manufactures, set to produce mechanic clocks, silk, paper, developing steel industry, started to use gold coins again. Though the devastating attack by the Mongolians

(1240–41) in the East (subjugating Russian principalities), the rise of the Turcs in the Near East represented a serious menace, this strengthened the cohesion of an *Occidens* now better including Poles, Czechs, and Hungarians; sided by a new South-Eastern Europe, a second Bulgarian empire of the Asens, a reborn Byzantium of the Palaeologues (1261–1453), an emerging Serbian state of the Nemanjides. A new expansion is imminent: ambassadors and travelers reach the Far East (Marco Polo: 1254–95), and Aragon is setting its regard upon North Africa, Norway is incorporating Island and Greenland.

The fourteenth-century is traditionally associated with 'crisis': famines, economic decline, the Black Death (1347–52), flagellant movements, pogroms, extinction of many royal dynasties (Arpadians – 1301, Přemyslsides – 1309, Capetians – 1328, Piasts – 1370), 100 Years' War (1337–1453), ravaging popular revolts (Jacquerie – 1358; Wat Tyler uprising – 1381). This is all true, but the image of 'waning' is wrong. It is only partly valid for the West, and is counterbalanced by the prosperity in Polish, Czech, Hungarian and Serbian Central Europe. The Prague of Charles IV (1346–78) becomes now the center of Europe. Drawing upon the richness of the Low Countries, the splendid court of Burgundy is living its 'epics of temerity and pride' (Huizinga). Despite the ravages of the plague, Italian cities remain prosperous. Following Dante (1265–1321), and Giotto (1266–1337), and Petrarch (1304–74) who saw himself already beyond the 'dark' Middle Ages, the *Decameron* of Boccaccio (1250) and *The Canterbury tales* by Chaucer (1390s) offer a rich synthesis of medieval narrative tradition. With all its crises, schisms, and new heresies, with the impact of Meister Eckhardt (1260–1328), St. Bridget of Sweden (1303–73), St. Catherine of Siena (1347–80), Wyclif (1330–84) and Hus (*c.*1370–1415) Christianity is preparing for the renewal of personal and secular religiosity.

The formidable new tensions and the grand achievements of the fifteenth-century represent the concluding period of this long Middle Ages. The power of the emerging new prophecies and religious anxieties is demonstrated by the explosion of the Hussite rebellion, by Joan of Arc who brings in 1429 a decisive turn in the Hundred Years' War, and by the beginnings of witch-hunts in Switzerland, Italy, and France. The political map of Europe is reshaped by the emergence of powerful new states. The Ottoman conquest is only temporarily slowed down by John of Hunyad and the crusade organized by St. John Capistran at Belgrade (1456). The formation of a multinational Central European empire, an endeavor of the Anjous, the Luxemburgs, the Jagiellonians, and Mathias Corvinus (1458–90), is finally realized by the Habsburgs with Maximilan I (1493–1519). A large Eastern Europe re-emerges with the Polish-Lithuanian Confederation and the new Russia of Ivan III (1462–1505). In the West, an impressive new state candidate, Burgundy, succumbs finally, and besides France of Louis XI (1461–83) and England of the Tudors after the Wars of Roses, a unified Spain of Isabel of Castilia (1474–1504) and Ferdinand of Aragon (1479–1516), and a miraculously ascending Portugal will be the states which lead the world-wide expansion of Europe in early modern times. Germany and Italy, on the other hand, have the largest share of inventions, richness, and culture, which made this expansion possible: the invention of printing by Gutenberg (*c.*1450), the banks of the Medici and the Fugger, the map of Toscanelli (1474) and the bold expedition of the Genovan sailor, Columbus (1492). The narrative must end here: a new story begins in the enlarged new world.

Middle East, North Africa: Sociocultural Overview

Seteney Shami, Social Science Research Council, Brooklyn, NY, USA; and The Arab Council for the Social Sciences, Beirut, Lebanon

Abstract

The Middle East, North Africa region, presents a complex heterogeneity of historical, social and political interconnections. This article begins with a brief overview of earlier scholarly approaches to the region and then focuses on the 1990s as a turning point that launched a new literature based on critical readings of both Orientalist and developmentalist approaches. Works over the past two decades have provided exciting insights into the workings of nation, gender, and religion in the region. However, there is still insufficient attention to issues of identity and difference that structure these societies and fuel much of its dynamics.

The term 'The Middle East and North Africa' (MENA) refers to a territory characterized by considerable diversity, extending from Morocco in the West to Iran in the East, spreads over Africa and Asia, and extending into Europe. This is a region that has given rise to the earliest forms of urban life and state organization in human civilization, produced three major monotheistic religions (Judaism, Christianity, and Islam), includes three major language groups (Arabic, Persian, and Turkish) as well as countless other languages and dialects, and exhibits sharp contrasts in physical and human geography. Since AD eighth century, successive Islamic empires have ruled and to some extent united this geographical expanse, the most recent of which was the Ottoman Empire. In other words, this is an area of great complexity, with its long historical record, literate traditions, and mixture of social and cultural groups.

In social science and humanities scholarship, this expanse was often seen as a region broadly sharing linguistic, religious, and cultural characteristics as well as a common geopolitical position in the world order. Yet, because of its complexity and diversity, the term and the territory associated with it are coupled in a shifting, unstable relationship. Afghanistan is sometimes included, sometimes not. The Sudan would fall in or out depending on whether the emphasis is on the African heterogenous south or the Arab Muslim north and it will be interesting to see how its recent division into two countries will impact the identification of North and South Sudan. Turkey is usually included, although many of its intellectuals and politicians prefer to find continuities with Europe and the Balkans, and/or with Central Asia.

The first part of the term, the Middle East, originates from nineteenth-century European, specifically British, strategic military divisions of the world. Other terms also compete for the same territories or carve it up in different ways: older terms such as the Near East or the Levant still have occasional currency, the latter having been proposed as a substitute term that emphasizes linkages, rather than boundaries, between the societies and cultures of the Greeks, Turks, Arabs, and Jews (Alcalay, 1993). Similar to this are arguments for the Mediterranean as a cultural unit. The term 'the Arab world' is often seen, especially indigenously, as more accurate in depicting an analytically coherent unit. In Arabic, the historical distinction between the Maghreb (the West, or North African countries) and the Mashreq (the East, or the Eastern Mediterranean countries) is widely used and this is reflected in French scholarship on the region, as exemplified by the journal Maghreb-Machrek. In German, the term 'the Orient' still largely refers to Islamic and Arab societies and the disciplines and learning related to them.

New regionalisms also compete with these designations in different ways. The renewal of historical and religious connections with Central Asia and the Caucasus, after a rupture of more than a century of Russian and Soviet rule, gives rise to new/old redrawing of the boundaries of the region. The freeing of scholarly imaginations by theories of globalization leads to the investigation of historical and contemporary links across the Indian Ocean with South Asia and Southeast Asia. Finally, studies of diaspora communities (e.g., Turks in Germany, the Lebanese in South America and Australia, the North Africans in Europe, Arab Americans, and so on) are beginning to look at translocal and transnational linkages that are also part of the making and unmaking of the region.

In the last decade or so, a renewed focus on 'Islam' perceived as a unifying and even homogenizing force has also redrawn scholarly boundaries. Despite the demographic reality that the largest numbers of Muslims do not live in the Middle East or North Africa, the region is inextricably linked with Islam as its historical fount and heartland. The ways in which some scholars now subsume Central Asia and parts of South Asia within the Middle East, on the basis of the 'Islamic nature' of their societies, as well as the resurgence of the term 'the Islamic World' shows how Islam is considered as a unifying force that brings together societies and histories with widely disparate historical experiences. Yet, the question of whether Islam, or any religion, can be seen as providing the sociocultural cohesion of a geographical region remains a problematic issue, as does the question of where the cohesive quality of Islam is to be located. Islam as a belief system? Or an institutional framework? Or historical experience? Or political ideology? The different answers lead toward different routes of comparisons and distinctions (Asad, 1986).

Turning Points

Lila Abu-Lughod's (1989) seminal review essay in the *American Review of Anthropology* marked a turning point in scholarship as it examined the important moves, theoretical and topical, that research on sociocultural issues in the MENA region had

made. Her three 'zones of theory' identified the dominant topics of the day to be as follows: tribe, women, and Islam. While she made clear the basis for these preoccupations in Orientalism as well as disciplinary 'prestige zones,' she also identified the advances that had begun to unmake these powerful scholarly legacies. Breakthrough works such as Edward Said's *Orientalism* (1978) opened up the door for a critical examination of the relations of knowledge and power that accompanies the dichotomy between East and West. Works began to meet the challenge of examining and historicizing the politics of representation, the most prominent being Timothy Mitchell's *Colonizing Egypt* (1988). From another angle, modernization theory and 'developmentalism' were being 'unmade' through new works in political economy and modes of production and through revising the received wisdom on the Ottoman and colonial periods, by focusing on the incorporation of the region into the world capitalist system as well as on nationalism and ideological currents in the area.

As one examines the scholarship that these new directions and frameworks yielded, one can identify not only continuities but also important shifts from Abu-Lughod's three zones of theory. Thus, works produced in the last two decades can be grouped under three main categories, which have seen the most growth in writing on the region, namely, nation, gender, and religion.

Nation

The ways in which national identity has been constructed in different parts of the region has been explored mainly in Turkey, Egypt, and Israel/Palestine, with some substantial work developing on North Africa. It is important to emphasize that work on the nation and nationalism, largely inspired by the work of Benedict Anderson (1983), is fairly new to sociocultural disciplines such as anthropology, whether in this region or elsewhere. This focus thus represents more a disjuncture than a shift from 'tribe' (as a metonym for all 'bounded' and 'local' groups) to 'nation,' and the transition between literatures has not been smooth. While rightly dismissing evolutionary paradigms (from tribe to nation), the new literature has largely not been able to address how the structures of the state are related to the production of locality and localism. More attention as to how the nation is imbricated in the local (and vice versa) would reveal the coexistence of alternative identities as well as differing readings of the nation by various social groups and communities.

Ethnographic work does focus, and in highly interesting ways, on history and memory as well as constructions of social categories such as the peasantry, notions of secularism and modernity, and the role of knowledge production and 'science' in the consolidation of nations (see Abu El-Haj, 2001). Also of interest are works on the past and present strategies of elites, roles of intellectuals and various occupational groups, the mobilization of different population groups, and the role of the media and other modes of communication in the construction of nationalism and of national and transnational public spheres (Shami, 2009). The work on expressive culture, distinction (in Pierre Bourdieu's sense), and representation is also growing both in anthropological and social historical works. The history of Arab nationalism presents a particularly interesting case, given that it is simultaneously produced in different locations such that inhabitants of 22 countries identify themselves as Arab in addition to identifying as Syrian, Egyptian, Moroccan, or Saudi (see *International Journal of Middle East Studies*, 2011). Arab nationalism is particularly illustrative of the transnational processes underpinning the production of nation, as well as the tensions produced by overlapping, and even competing, nationalisms.

Arguments about the nation in the Middle East have been especially interesting where they concern the intersection of the individual and the national, the private, and the public selves. Also significant here is the literature on the politics of memory and the ways in which the stories people recall transform individual memory to something more public and national. Ethnographic narratives also contribute to the understanding of the role of the arts and media in the construction of nationalism. The instrumental cultural and political roles of entertainment media, for example, television melodramas, in the production of national culture and the molding of individuals into modern national citizens, are the focus of a growing number of works.

While the literature on nation focuses on the construction of a national and collective identity, especially in the ways that body, self, family, sociability, and citizenship/participation are transformed, less explored are the political and discursive processes of foregrounding certain identities and erasing others that lie at the heart of any national project. National identity is premised on the existence of a 'majority' with varying degrees of tolerance for those who would then be cast or cast themselves as a 'minority.' Those who embody the nonmajoritarian identity are often left understudied, making ethnographers complicit with the nations that they study in imagining that a majority exists and is fashioned out of a collectivity that is premodern. In other words, ethnic identity and minority populations, if noted, are seen as vestiges of the premodern, and thus displaced and out of place in the nation.

It is in places where the contradictions between past and present are too sharp to ignore, and where the politics of recognition throws up powerful competing claims, that national projects can be best deconstructed through critical research. The palimpsest that is Palestine is the prime example. In the story of the town of Ein Houd/Ein Hod, Susan Slymovics (1998) gives an account of two peoples, Palestinian Arabs and Jewish Israelis, who cultivate the link between memory and place, and the sense of loss permeates the narrative at every level. Her book, *The Object of Memory*, is not only about dispossession but also about active remembrance. Slymovics situates Palestinian memory in the larger genre of memorial books produced by those who have suffered war, dispersion, and traumatic loss as they strive to construct a nation, a community, through the links between memory and place (see Naguib, 2008). Other works on Palestine/Israel, whether focusing on places or people, begin to unpack the overlapping and contradictory processes of nation-making and the inclusions/exclusions and fashioning/erasures that are at work.

The literature on Turkey is similarly fascinating in both erasing and celebrating Kurdishness depending upon context,

thus echoing political positions often taken by progressive secular elites. Many of the excellent works on Turkish nationalism that focus on state projects of remaking gender, family, domesticity, and citizenship somehow elide the issue of ethnic differences, although this becomes manifestly the object of research when studying how Kurdishness is constructed against an imagined Turkishness.

Recent works on Sudan, the Gulf States, Syria, and Cyprus all have begun to explore the fluidity of identities and the politics of ethnicity and nationalism, making clear the urgency of such processes. While Lila Abu Lughod (1989) rued the focus in anthropology on 'peripheral' places (such as Yemen and Morocco), the power of the margins in unmaking hegemonic discourses (including academic discourses) is never clearer than when looking for traces of occluded identities.

Gender

The literature on gender roles and relations has perhaps witnessed the most robust growth and generated interesting discussions on the region. Starting in the 1970s, particularly following Cynthia Nelson's 1974 article in which she challenged the stereotyped images of women succumbing to patriarchal rule with docility and passivity, the theme of women as victims of patriarchy and Islam has been replaced by narratives of women as agents who negotiate their own survival. This survival takes place, in part, by 'bargaining with patriarchy' (Kandiyoti, 1996). A burst of work on women appeared in the 1980s, as covered in Lila Abu-Lughod's 1989 *Annual Review of Anthropology* review, which aimed at moving beyond simply debunking stereotypes to constructing theory. Contemporary trends in the literature further move from a focus on women to the study of gender, including the construction of gender identity and notions of femininity and masculinity; the fashioning of the body through economic power, political participation, violence, and war; and women's enmeshment in national and transnational processes. This work has yielded insight not only into how male and female persons are culturally constructed, but also into female contributions to the construction of larger social identities. Interestingly, recent work focuses mostly on the Arab 'Mashreq' region, with a heavy focus on Egypt, and there are astonishingly few ethnographies of gender in Turkey. Anthropological research on Iran remains difficult under current political conditions, and the work on gender is often through the lens of 'youth' or takes cultural production, and especially film works, as its main ethnographic texts (Varzi, 2008). However, Homa Hoodfar has important works on gender in relation to Islam, citizenship, and reproduction in Iran (2000, 2001).

Thus, a number of scholars have examined the lived experience of gender subordination in a hierarchical system, including work on ritual, marriage, and households and socializing practices. Women's political activism and participation, particularly under conditions of conflict, has also formed the focus of a number of noteworthy monographs.

Gender relations and gender identity have also been a central focus of medical anthropology in the region in the past 20 years, largely with a focus on Egypt. The relationship between gender differentiation and ideas of sickness and health in rural Egypt has been examined as well as reproduction and motherhood as major practices through which women create their gender identity, impacted by other vectors of identity such as class and religion. Fertility and reproduction articulates with national identities and state policies for shaping citizens and several works in medical anthropology have included a focus on maleness and the body and bring in regional, transnational, and global processes as well. Studies include men's roles in systems of hierarchy and domination, whether within communities of study, in a national context, or in contexts of national or global conflict and inequality. There has also been a trend toward studying male and female roles in gender relations concurrently, particularly within the family as highlighted by Suad Joseph and Susan Slyomovics in their introduction to *Women and Power in the Middle East* (2001).

As can be discerned, an important theme in much of the above-mentioned work attends to the ways in which gender identity articulates with communal and national identities on the one hand, and global processes on the other. The two most disappointing aspects of this otherwise exciting literature are, first, its almost exclusive focus on Muslim women, and, furthermore that, in the exploration of family, nation, body, etc., various types of differences other than gender differences are erased. This makes the work of Anita Fábos on the Sudanese in Cairo quite unique (2008), with its focus on *adab* or propriety and practices such as female circumcision in the context of the cultivation of Sudanese identity in the particularly ambiguous zone of Egyptian–Sudanese relations. Also revealing is the work on female migrant domestic workers of Southeast Asian origin working in Arab families (Moors et al., 2009). The analysis of how the incorporation of 'foreign' women into the intimate domestic sphere brings into question national, racial, and religious identities is promising for exploring a new challenge to ethnic boundaries, those within the home itself and in the 'private' sphere. While hitherto the focus in this regard has been on religious dimensions, especially when differing practices of Islam come face to face within the domestic sphere, the same perspective can be applied to other aspects of gender relations and roles.

It has long been recognized that gender relations and gender identities are central to constructing and perpetuating collective identities, including national, ethnic, and minority identities. For the MENA region, this has been often explored through visual culture, for example, in the excellent works by Viola Shafik (2007a, 2007b) on Egyptian cinema. One looks forward to a more robust study of gender dynamics as they intersect and interact with different types of collective identities on the one hand and local contexts on the other.

Religion

The works on gender and religion intersect in important ways, as a major trend in the past 20 years has been a focus on women and Islam, with a growing recent interest in Shi'a women. Both Ziba Mir-Hosseini (1999) and Lara Deeb (2006) examine the construction of religious discourse and women's

participation in constructing discourse about themselves. While Mir-Hosseini focuses on the construction of religious discourse about women, Deeb considers how women themselves participate in authentication, or actively defining faith in daily life and discursively establishing religious authority not only about women but also about Islam. The ideal for women in the religiously observant Shi'i community she studied was that of public piety.

Several major interventions on Islam have influenced much of the literature of the past 20 years, for example, Talal Asad (1986, 1993), Michael Gilsenan (1982), Sami Zubaida (1995), and Daniel Varisco (2005). Unsurprisingly, there is particular ethnographic attention to Islamism or fundamentalist Islamic movements from their appeal to 'vernacular politics' (White, 2002) to women's piety movements (Mahmood, 2001, 2005). Mahmood questions ethnographic depictions of women's agency and feminist goals and argues that there is a tendency to look for resistance and challenges to male domination even when they are difficult to locate. Based on research with a women's organization in Egypt, Mahmood calls for a notion of agency that can account for women's active pursuit of ideals considered illiberal and regressive within a Western feminist discourse, such as certain Islamic ideals of female piety and modesty. Her ethnographic study exposes assumptions of both feminist theory and 'secular-liberal thought' about the nature of the self, agency, and politics, as well as assumptions about the relationship between interiority and performance.

From the other end, state responses to Islamist movements and governments' attempts to shape a particular type of Islamic identity are also the focus of study. The most thorough work to consider religion and politics in a multisectarian environment is Joseph's (2000) research in Lebanon examining how sect endogamy and the 'civic myth' of sectarian pluralism obscures the working of kin endogamy and patriarchy encoded in personal status law and sanctioned by the state. Hale's work on women's participation in both secular and Islamist politics in Sudan is exceptional in its scope. Rather than focusing her gaze on one or the other, Hale productively examines how both secular (Communist) and religious (Islamist) national parties objectify women (Hale, 1996).

In spite of this literature, in comparison to other topics, there are fewer monographs focusing on religious identity than the prominence of religious revival movements in the region since the 1970s would seem to warrant and much of the literature neglects the question of how different groups in society may articulate their Islamic identity and piety in ways that vary significantly from one another. Even works supported by rich and valuable ethnographic detail sometimes seem to treat 'Islam' and the 'Islamic Revival' as monolithic categories and processes. A neglected topic within the study of the resurgence of both political and personal Islam is how changing perceptions and practices of Islam intersect with other identity factors, including ethnic and linguistic identities. It is important to note that Islamic identity may act as a unifier across ethnic and other differences in some contexts, while in others it can conversely exacerbate such differences as well as fuel competing sectarian identities. The lack of studies on interreligious interaction or in-depth ethnographies of communities with mixed religious populations is almost inexplicable. Thus Christian and Jewish communities, when studied, are usually dealt with as though separate and self-contained.

Identities and Differences

While the literature on nation, gender, and religion (read: Islam) examines important major sociocultural processes in MENA societies, there is a general tendency to collude with the 'national order of things.' The 'nation' is discussed as the property of the majority with little attention to minority groups, or how notions of 'majority' and 'minority' are constructed in the first place. While the literature on gender identities, roles, and relations is rich and nuanced, the social and cultural context is almost always an 'unmarked' Muslim national grouping. When religion is the focus, Islam clearly dominates work on the region and remains mostly on the majority religious group (Sunni or Shi'a) to the occlusion of other Muslim and non-Muslim groups in the country or region.

The relational quality of identity construction and the structuration produced by the construction of difference are usually mentioned cursorily if at all. Religious minorities for the most part are only seriously discussed if they are the specific group under study. Thus, ethnographies that do discuss non-Muslims, mainly Christians, tend to treat them almost incidentally as part of the broader society. For example, there has been no ethnographic work on religious practice among Christians in the MENA region. There are almost no cultural analyses of how nationalism is perceived and reproduced (or resisted) among non-Muslim groups.

A small literature does specifically focus on particular ethnic, religious, and linguistic groups, clustered around quite specific geographies and groups. In the work on Iran and Afghanistan, there is a literature on various ethnic and linguistic groups. The fact that many of these constitute quite distinct pastoral nomadic groups constitutes both a problem and an interesting trajectory of research. As an illustration, while nomad–settler relations constitute an important focus in ecological and economic research on various hinterlands, few such studies take into account the often different ethnic and linguistic identities of the nomads and settlers involved. In contrast, earlier work on Iraq, such as by Amal Rassam, also known as Vinogradov, showed great promise in focusing on the mutual brokering of economic and ethnic relations and social hierarchies in rural settings (Vinogradov, 1974; Rassam, 1977). Current work on Kurds and Kurdistan, including historical works, similarly shows promise despite being few in number.

Another focus of research that promises new directions in the understanding of identity and difference is on Sudan and Egypt. A flurry of research was carried out in the 1960s by anthropologists at the American University in Cairo on Nubians of the Aswan region, in response to the massive relocations taking place in the wake of the construction of the Aswan Dam. However, for long the categories of 'Nubian' and 'Arab' remained largely unexamined in these contexts. Recent work, however, has begun to examine Nubian identity and its expressions in various settings, rural and urban. This opens up a brand new avenue of research in the region, namely, on 'race.'

This includes social historical works such as by Eve Troutt Powell (2003), pointing the way to nuanced cultural analyses of the intersections of race, ethnicity, and nation in historical and contemporary contexts.

Similarly, work on the cultural politics of 'Berber' (or Amazigh) identity focuses attention particularly on linguistic and symbolic aspects of Berber–Arab interactions. In the way that the literature on Egypt/Sudan leads us to race, the North African literature alerts us to the topics of migration and diaspora (Silverstein and Goodman, 2009). In addition to North African migrations and the politics of identity in Europe, the ethnographic gaze also shifts to the Arabian Peninsula and the Indian Ocean. Migration and displacement continue to frame the lives of a majority of the population of the region, directly and indirectly. Refugee's study is now a growing field, given that the region has produced as well as hosted some of the largest refugee populations in the world.

The most exciting literature that looks at history, diaspora, and identity should inspire generations of students. We can add to this the study of groups and communities originating from the Middle East and living in the West. In the emerging literature from the Middle East on diaspora we see two strands of research: one that connects to the ethnographies that draw on the politics of memory in contested places, the second belonging to studies connecting history and anthropology. In both approaches, writings illuminate everyday life and tell us more about how history, memory, and events impact people's everyday life. These works are examples of how personal, familial, or local memories may explicitly or silently challenge official versions of national history.

Drawing inspiration from works on memory, anthropologists working on contested sites and particular social or cultural groups are exploring the 'politics of memory' and the significance of memorializing practices to the politics of the nation and the state. Such explorations have been fruitful in understanding the role of commemorative practice in producing or reinforcing political ideologies of ethnic or religious group solidarity. Anthropologists have shown the myriad linkages between communal rituals and state policies in their historical unfolding. Connections are made between works of memory, colonial history, and political dislocation, demonstrating the centrality of political autonomy to the possibility of performing commemorative acts in postcolonial contexts or under repressive state regimes.

Conclusion

The study of sociocultural processes in the MENA region has progressed immensely in the past two decades and is much richer than previously, both in terms of the phenomena examined and the analytical frameworks deployed. This article has organized the discussion of the region through a focus on three major areas of research (nation, gender, and religion/Islam) that illustrates both continuities with past scholarship as well as the robustness of new and critical frameworks of analysis. The argument throughout, however, is that there is insufficient attention to issues of identity and difference in the region, which leads to slippages and easy generalizations (Shami and Naguib, 2013). A keen historical sensibility is needed to capture the ways in which these identities unfold and transform over time and through different contexts. In addition, the politics of state and nation building (which both involve transnational processes) must be the context through which the production of ethnic categories is understood. And finally, the transnational networks and exchanges within which identity formation is linked through migration and the formation of diasporas must also be taken into account. In the steadily growing literature on migration, one has possibilities to explore transformations and transnationalizations that aspire to legitimacy and recognition by both the state and supranational or international institutions.

This intellectual project takes on renewed urgency with the dynamics unleashed by the uprisings in the Arab region starting in late 2010. New forms of knowledge about identity and difference in this region are central to the new social imaginaries that are emerging and being contested in city squares and streets everyday. At the same time, the somber reality of sectarian and ethnic violence is also present, showing up the poverty of previous discourses of national identity and their inability to be truly inclusive. The drama being played out opens up possibilities to take up old debates and start new conversations about relationships between men and women, social classes, minorities and majorities, generations, and between citizens and the state.

Middle Eastern and North African Legal Traditions

Lena Salaymeh, University of California (UC) Berkeley School of Law, Berkeley, CA, USA

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Legal systems in the modern Middle East and North Africa are both diverse and hybrid. This article provides an introductory overview that summarizes the multilayered legal history of this region and discusses how imperialism and colonialism shaped legal reform movements, codification, and the secularization of law.

Introduction

The common phrase/name 'Middle East and North Africa' (MENA) combines political and geographical categories. The 'Middle East' is a problematic political (rather than geographical) category; in comparison, 'North Africa' is a useful geographic category. While the more geographically descriptive (and less geopolitically constructed) term 'Southwest Asia' (or 'Western Asia') is preferable, it is not in widespread use. The 'Middle East' is an ambiguous, shifting, and modern (specifically, beginning in the twentieth century) category, having historically been preceded by the term 'Near East' (a term disseminated through British colonialism). Indeed, "The Middle East exists because the West has possessed sufficient power to give the idea substance. In this regard the colonial past and imperial present are parts of the equation that make the Middle East real" (Gasper, 2012: p. 240). Consequently, this article will focus on the modern period and modern nation-states. States that are often included within the 'Middle East' include Armenia, Bahrain, Cyprus, Egypt, Iran, Iraq, Israel, Jordan, Kuwait, Lebanon, Oman, Palestine, Qatar, Saudi Arabia, Syria, Turkey, United Arab Emirates, and Yemen. States that are typically included within 'North Africa' include Algeria, Libya, Mauritania, Morocco, Sahrawi Arab Democratic Republic, Somalia, Sudan, and Tunisia. This article will not comprehensively discuss the legal systems of each of these states, but instead offer a broad overview of the region with some detailed attention to the legal systems of some representative states. The acronym MENA will be used throughout this article to refer to the Middle East and North Africa. It should be noted that the MENA region is ethnically, linguistically, and religiously diverse; it cannot be simplified as the Arab or Islamic world.

Pre-Islamic History

Historical evidence that survives from some of the oldest legal systems globally comes from the Near East. Several ancient legal systems operated in the Near East and parts of North Africa, including the laws of Uru Nammu (twenty-second century BCE), Sumerian laws (eighteenth/nineteenth century BCE), laws of Hammurabi (eighteenth century BCE), Middle Assyrian laws (eleventh/twelfth century BCE), and many other legal systems (Jackson, 2008: pp. 37–44). In North Africa, Berber and Roman legal traditions were practiced for centuries. These and other ancient sources indicate a long history of complex legal systems operating in the region.

Islamic History (*see* Islamic Law)

Islam spread throughout the MENA gradually, over several centuries, as the result of conquests, trade, and assimilation processes. The majority of the region's inhabitants did not become Muslim until the medieval era (some estimates are between the twelfth and fourteenth centuries, depending on local circumstances). Throughout premodern history, non-Muslims (particularly Christians and Jews) operated their own courts to adjudicate matters of personal status (such as marriage, divorce, and inheritance) for their constituents. Still, non-Muslims frequented state (i.e., Islamic) courts for a variety of legal issues (including personal status). Since its historical beginning, Islamic law has had two overlapping dimensions in the MENA region: the first is the application of Islamic law as a state legal system over all its subjects; the second is the application of Islamic law by private jurists or Muslim associations (unaffiliated or unregulated by a state) over Muslim subjects. The first dimension is discussed in another encyclopedia article, Islamic Law; the second dimension will be mentioned briefly throughout this article.

Imperialism and Legal Reform (Eighteenth to Nineteenth Century)

The imperial era in the MENA region began in approximately 1798, with the Napoleonic invasion of Egypt (Mallat, 2007: p. 132). The people of the MENA region radically altered their legal systems between the eighteenth and twentieth centuries as a result of foreign intervention and internal demands for reform; the two factors cannot be easily distinguished. Legal changes that began during the Ottoman Empire intensified after its disintegration, the establishment of colonial regimes, and the later founding of quasi-independent nation-states. These legal changes primarily resulted in the emulation of the legal systems of European states, particularly in terms of juristic training, court procedures, and jurisprudential methodologies.

Tanẓīmāt (reorganization) is the term used to describe a period of reform in the Ottoman Empire that is typically dated as beginning with the Hatti Şerif of Gülhane (Imperial Edict of the Rose Chamber, known as the Gülhane Rescript)

of 1839 and ending with the Reform Edicts of 1856, but can be extended to describe legal changes beyond that date. The Gülhane Rescript confirmed the civil and economic rights of all Ottoman subjects, while confirming Islamic law as the source of Ottoman law; it is perceived as symbolizing Ottoman pluralism because it erased legal status differences between Muslims and non-Muslims. In 1847, the Ottomans established courts with both European and Ottoman judges, applying a combination of European and Ottoman laws and procedures. Several codes were promulgated in this period that largely adopted European (especially French) codes: in 1850, a commercial code; in 1858, land and penal codes; in 1861, another commercial code; and in 1863, a maritime code. These Ottoman codes were based on French law and were implemented by state courts (*niẓāmiyyah*). In addition to the enactment of codes (primarily instigated by European demands), Ottoman courts adopted European procedural rules and created special courts to adjudicate cases for Europeans. After 1869, the Ottoman Empire followed a civil code known as the *Mecelle-i Ahkam-i Adliye* (hereinafter, the Ottoman civil code), which included both Islamic legal principles and a variety of Islamic substantive and procedural laws, but was structured like the French Civil code. These modifications in the Ottoman legal system created a demand for jurists trained in these new codes and European-influenced legal procedures, resulting in the undermining of traditionally trained jurists.

Imperialist intervention in the legal systems of the region is most evident in the capitulatory system that was imposed upon the Ottoman Empire. European governments had placed significant pressure on the Ottoman Empire to provide their consuls with jurisdiction over all legal issues involving Europeans – and their affiliates, who included non-Muslim subjects of the Ottoman Empire – doing business in the Ottoman Empire. By the end of the eighteenth century, European capitulatory privileges were significantly affecting Ottoman markets as commercial dealings were effectively governed by external, foreign powers. Foreign legal jurisdiction in Ottoman Turkey did not end until the 1923 Treaty of Lausanne ratified the independence of Turkey.

Colonialism, Codification, and Modernity (Twentieth to Twenty-First Century)

The post–World War I division of the Ottoman Empire by the British and French created the modern nation-states that are now identified as MENA states. The 1916 Sykes-Picot agreement divided most of the areas previously under Ottoman rule into British and French colonies. Colonial administrators composed handbooks or legal guides for the MENA region throughout the nineteenth century; these texts shaped how colonized subjects viewed law in general and Islamic law in particular. Each newly formed state in the MENA region pursued an individualized path to establishing a state-based legal system that simultaneously reflects both the state's particular circumstances and broader trends of Westernizing law to meet global financial and political pressures. After the dissolution of the Ottoman Empire, the independent state of Turkey began a process of 'secularizing' its legal system through the adoption of European codes.

ʿAbd al-Razzāq al-Sanhūrī (d. 1971) spearheaded the codification of Egyptian civil laws in 1948, by fusing French and Egyptian legal norms. Sanhūrī was the most influential legal reformer in the Middle East in the twentieth century. A more comprehensive Egyptian Civil Code was promulgated in 1949 and it encompassed all civil legal matters, except personal status; it was based on a variety of civil codes from other countries and Islamic legal traditions. Many Arab states adopted Sanhūrī's codification with little or no modification. Egypt's civil code was replicated in Syria in 1951, in Iraq in 1953, and in Jordan in 1976. In 1951, Sanhūrī himself became involved in drafting Iraq's Civil Code, which, according to some scholars, contains more Islamic norms than its Egyptian predecessor. The introduction of legal codes throughout the region was met with little popular resistance, probably because most states divided jurisdiction between Islamic and civil courts – with the former handling the kinds of domestic cases that affected the broadest population base. There was significant scholarly discussion and commentary on, and explanation of these codes by contemporaneous jurists. In North Africa, French-inspired civil codes were the norm, with Islamic law influencing (although not necessarily dictating) family law codes.

The independent postcolonial nation-states that emerged in the MENA region implemented legal systems primarily based on Western legal systems. However, since most (if not all) of the states in the region were authoritarian, one should be cautious in drawing conclusions about the operation of law in isolation from the political context. Indeed, some observers have noted that the authoritarianism and military conflicts prevalent in the region puts into question the efficacy of the rule of law.

Colonizing Property Law, Liberalizing the Economy

In the nineteenth and twentieth centuries, land became increasingly privatized in the region as part of an extensive process of integration in the global capitalist economy. In the early nineteenth century, a series of legal decrees were enacted to facilitate the transfer and privatization of property. The Ottoman Land Code (1858) identified five types of property: (1) privately owned land; (2) state-owned land under private administration; (3) charitable-endowed trusts; (4) public land under preservation; and (5) land beyond the boundaries of inhabited areas. Regulations for each property type were designed to facilitate transfer and privatization of property. Other local land laws modified the prevailing conditions of land ownership. In order to control property in Algeria, the French waged a campaign against lands held in trust that entailed attacking the Islamic legal tradition of endowments (*awqāf*) (Powers, 1989). Western scholarly attention to Islamic trusts and laws regulating private property in the modern MENA reflect a wide-ranging interest in the history of global capitalism; unfortunately, some of this scholarly interest legitimates a problematic assumption of the incompatibility between Islamic law and modern financial structures (or economic progress in general) (Salaymeh, 2014). In the twentieth century, imperialist pressures on law reform in the region are evident in a variety of commercial laws (foreign investment, banking, taxation, employment, intellectual

property, and taxation) designed to integrate the MENA into the 'global economy' (Lapidus and Salaymeh, 2014).

Colonizing Family Law, Liberalizing Society

The long history of Western intervention in the legal systems of present-day MENA nation-states makes family law a battleground for far-reaching political issues. Colonial officers throughout the MENA region directed much criticism to the organization of families. In response, some local legal professionals sought to emulate Western personal status laws, while others rejected Western models. Enacted in 1917, the Ottoman law of family rights included a broad array of legal opinions from majority, minority, and extinct Islamic legal schools and was the first 'modern' family law code, applied throughout the empire. Turkey replaced the code with secular reforms in the 1920s. Other former Ottoman provinces replaced it with national family law codes – such as in Jordan (1951) and Syria (1953). Personal status codes were enacted throughout the region in quick succession: Tunisia (1956), Morocco (1958), and Iraq (1959). While these modern laws primarily codified Islamic legal norms, they also imposed the state's bureaucratic apparatus by requiring court involvement or registration of all marriages and divorces. In Egypt, the 1897 code for Islamic courts made written registration of marriage, divorce, and inheritance incumbent; this was confirmed by a later law requiring official documents for all family law matters after 1911. These procedural rules had substantive outcomes, since the courts were thereby able to implement a variety of previously informal or unenforced restrictions – such as a minimum age for marriage.

Marriage and divorce laws are the principal sites of contestation between groups that are erroneously labeled as 'conservative' and 'reformist/liberal'; this label oversimplifies the complex stakes that animate why individuals or groups advocate for particular laws. What underlies conflicts about family law is the sociopolitical reality of neoimperialism: many people in the MENA region view Westernized legal 'reforms' as a type of foreign intervention and therefore view rejection of Western legal norms as a form of resistance (Salaymeh, 2014; Lapidus and Salaymeh, 2014).

Islamicizing Constitutions in the MENA Regions

There is a broad spectrum of constitutional recognition of Islamic law in the MENA. Turkey declared itself a secular state in 1937, after removing constitutional reference to Islam as the state religion in 1928. Syria's 1973 constitution does not identify a state religion. After the 1979 revolution, the Iranian Constitution made Islamic law the highest source of legal authority and made Iranian jurists an integral part of the government. Based on its own determination of Islamic suitability, the Iranian Council of Guardians (comprising 12 jurists) is responsible for interpreting the Iranian Constitution, has the ability to overrule any legislation, and can prevent candidates from participating in political elections. Pakistan declared Islamic law as more authoritative than its own constitution in 1991. To understand what these constitutional references (or lack of references) to Islamic law mean or how they operate, it is essential to examine actual case law. All states in the region incorporate a hybrid of secular and religious laws and institutions. Most states apply Islamic law in distinct ways and generalizations cannot be made about the role of Islamic law in a particular modern nation-state based only on the text of its constitution.

Most importantly, the overt religious/secular characteristics or structures of states do not necessarily shape the substance of a state's legal system. In contemporary political discourse, demands for the inclusion of Islamic law in the constitutions of nation-states with Muslim majority populations has become commonplace. This rhetoric must be understood within its complicated sociopolitical context: continued foreign intervention, undemocratic regimes, and limited social and economic mobility. Popular Islamist movements pose a serious threat to essentially secular, autocratic regimes. Moreover, the term Islamic law means different things to different people and is often a symbolic – rather than substantive – demand. Typically, demands for the enforcement of Islamic law are simply demands that particular orthodox or historical Islamic laws – particularly in the areas of family and criminal law – be applied. The integration of Islamic law in the legal systems of modern nation-states has a minimal impact on the daily operation of law because the preponderance of legal matters (in civil and commercial matters) is governed by 'secular' laws.

Brief Legal Histories and Summaries of Select States

The following descriptions of the legal systems in certain MENA states focus on national legal systems, without delineating an individual state's international treaties or ratification of international agreements. Most MENA states have adopted civil legal codes, with some inclusion of Islamic law – particularly in the areas of personal status. The majority of these states have extensive and continuously updated laws concerning commercial activities, civil and criminal procedure, banking, property, taxation, and environmental protection that are not delineated here. Commercial laws in the region are essentially consistent with global practices, which are dictated by the strongest economies (mostly Western states) and designed to meet the demands of foreign investors and workers. Generally, labor laws – especially for foreign workers – are weak and employees have limited legal protections from exploitation. It should be noted that many states in the region recently enacted antiterrorism laws (modeled after those implemented in Western states) that function not as a form of crime prevention, but as a restraint on dissidents with Islamist political leanings. These legal synopses are not intended to be exhaustive in their presentation of the breadth of these legal systems.

Algeria

France colonized Algeria in 1830, beginning more than 30 years of French intervention in Algerian law – epitomized by the 'Droit Musulman-Algérien,' which was a fusion of French and Islamic laws. (Similarly, Anglo-Muhammadan law was a combination of British and Islamic laws that British judges applied to Muslims until 1947.) France imposed a hierarchical court system and a draft code (Code Morand of 1916) that

Europeanized Islamic laws; the Code Morand was a 'modern' interpretation of Islamic legal principles that was very influential on Algerian law.

Algeria achieved independence in 1962 and adopted a constitution in 1963 that was amended in 2002 and in 2008 (Kebir, 1994: p. 397). The Criminal Code (1966) integrated much French law. The Civil Code (1975) combines French and Islamic laws (Kebir, 1994: p. 397). The Family Code (1984) combines Islamic and non-Islamic laws and was modified in 2005 (Kebir, 1994: p. 404). Algeria's judicial hierarchy includes a Supreme Court, courts of appeal, and courts of first instance (Kebir, 1994: p. 400). After a civil war from roughly 1990 to 2000, the Algerian government criminalized an array of activities related to political Islamism under the pretext of 'fighting terrorism' (Kebir, 2000–2001: p. 364).

Bahrain

Bahrain gained independence from Britain in 1971 and its legal system fuses civil law (from the Egyptian civil code) and common law (from English laws of contracts) (Al Baharna, 1994: p. 332). Bahrain's criminal procedure code (1966), penal code (1976), and various commercial codes constitute the bulk of the state's laws. Bahrain's 1973 constitution gives a Council of Ministers and the Amir (or King) the authority to issue legislation. A consultative council was established in 1992 to provide legislative support and offer advice to the government (Al Baharna, 1994: p. 333). The constitution was replaced in 2002 with a new constitution declaring that the state of Bahrain would be named the Kingdom of Bahrain and issuing a series of laws (Al Baharna, 2001–2002). Bahrain's judicial hierarchy includes the Supreme Court of Appeal (established in 1989), the High Court of Appeal, the High Court, and the lower courts (Al Baharna, 1994: p. 335). The Bahraini uprising that began in 2011 demands a representative form of government and protection of basic human rights.

Egypt

Modern European (particularly French) civil law codes were integrated into the legal system of the Egyptian state in the nineteenth century. New legal codes (civil, commercial, maritime, criminal, and procedural) promulgated in 1875 combined the *Code Napoléon* and Islamic legal sources. Mixed courts were established in 1875 to adjudicate matters between Egyptians and foreign nationals on the basis of these codes; they continued to operate until 1949. Similarly, based on European models, National Courts and national codes were established in 1883. Egypt's Civil Courts have a structured hierarchy of appeals: two categories of the Courts of First Instance, Courts of Appeal, and the Civil Chamber (Kosheri, 1994: p. 125). The Egyptian government began training judges for its new Islamic courts in 1907. Egypt's Islamic courts were integrated into the National Courts in 1956.

One of the better known modern legal reformers was ʿAbd al-Razzāq al-Sanhūrī (d. 1971), discussed above, who led the drafting of the Egyptian Civil Code (1948/9) and the Iraqi Code (1951) and participated in the drafting of codes for neighboring states (including Iraq, Syria, Jordan, Kuwait, and Libya). Sanhūrī earned two doctorates from the University of Lyon, was dean of both an Egyptian and an Iraqi law school, and held several government positions. Sanhūrī sought to modernize Islamic law and to develop a modern legal system that would benefit from comparative study of Western legal systems, but emphasize Islamic values.

Egypt's 1971 Constitution established a Supreme Constitutional Court (SCC) and an independent judiciary. (Amendments to the Egyptian constitution were enacted in 2007.) The SCC hears cases through referrals from lower courts (criminal, civil, or administrative) and its decisions are irrevocable. In response to popular demands, the Egyptian Constitution was amended in 1980 to identify Islamic law as 'the' (rather than 'a') primary source of Egyptian legislation. The 2011 Egyptian Constitutional Declaration identified the principles of Islamic law as the principle source of legislation. In the Egyptian legal system, substantive Islamic law is most influential in family law. For example, in 2000, Egypt enacted a law facilitating wife-initiated divorce that was challenged as an unconstitutional violation of Islamic law; the SCC upheld the law, noting that there are valid Islamic legal opinions validating such divorces (Riad and Gabr, 2002–2003: pp. 181–194). While non-Muslims (primarily Copts) are governed by non-Islamic laws of marriage and divorce, they are subject to Islamic inheritance rules. Egypt's family laws of 1920 and 1929 were updated in 1985 (Kosheri, 1994: pp. 139–140). Islamic law does not appear to have much influence on Egypt's Penal Code.

A number of business-friendly laws were passed in the 1970s and 1980s to encourage investment in line with global capitalist trends. Law No. 203 (in 1991) initiated a slow process of privatization, supported by laws that reorganized the banking system (Kosheri, 1994: pp. 130–131). Further liberalization of Egypt's economy was instituted through Law No. 38 (in 1994), which deals with foreign currency and exchange (Kosheri, 1994: p. 133). Egypt's 1952 revolution had resulted in redistribution of land; a series of laws were passed in the 1990s that reflected broader liberalization efforts on the part of the Egyptian government (Kosheri, 1994: p. 139). Egypt's 2011 revolution and 2013 military coup have created an uncertain future for the rule of law in the state.

Iran

Modern Iran was ruled by a monarchy until the 1979 revolution, which established the Islamic Republic. The establishment of an Islamist government did not immediately alter the legal landscape of the country; specifically, some legal codes predate the revolution, including the Civil Code (1928–35) and the Commercial Code (1932). The Iranian Constitution (1979; amended and ratified in 1989) gives jurists – whether the supreme leader or the Council of Guardians – prominent roles in the state's law-making, including judicial review. The Iranian Parliament drafts laws that are reviewed by the Council of Guardians (Ansari-Pour, 1994: p. 385). In 1989, Iran created a council to mediate between the Council of Guardians and Parliament, in an effort to resolve an impasse between jurists and legislators. The Council of Ministers also drafts laws that are sent to Parliament (Ansari-Pour, 1994: p. 386). While the Imāmī Shīʿī school is the official source of law, other Islamic and non-Islamic laws are recognized by the state. Iran's 1911

criminal procedure code was replaced in 1999 (Ansari-Pour, 1999–2000: p. 335). The civil procedure code (1939) was replaced in 2000 (Ansari-Pour, 2000–2001: p. 349). An Islamic punishment code was promulgated in 1991 and a 1994 act resulted in some changes to civil and criminal procedures (Ansari-Pour, 1994: p. 386).

Iraq

Iraq's 1925 Constitution confirmed its monarchy and established a legislature, but Iraq did not become independent of British rule until 1932. The 1958 revolution established a republic and the Iraqi Constitution was modified repeatedly (in 1943, 1958, 1963, 1965, and 1970) (Al-Mukhtar, 1994: p. 158). In addition to the executive, judicial, and legislative branches, the Constitution enumerates the duties of the Revolutionary Command Council, which had supreme authority in the country. Iraq's judiciary includes civil, criminal, family, and special courts; the Court of Cassation is the highest Iraqi court (Al-Mukhtar, 1994: p. 160). Iraq's Civil Code was promulgated in 1951, under the direction of Egyptian jurist ʿAbd al-Razzāq al-Sanhūrī, and reportedly contained more Islamic legal principles than its Egyptian counterpart (Al-Mukhtar, 1994: p. 163). Civil procedure, evidence, commercial law, banking law, and employment law correspond to European civil legal systems or other Arab legal systems. Family law was governed by the 1959 personal status law and is applied to all Iraqi Muslims; Iraqi Christians, Jews, and other confessional groups have their own personal status laws that are applied in the civil courts.

Iraq issued a series of new laws and modified existing ones in the period prior to its occupation of Kuwait (Al-Mukhtar, 1994: p. 171). As a result of the United States–led invasion of Iraq in 1991 and its occupation in 2003 (which ostensibly ended in 2011), the country's legal system was effectively destroyed. Iraq's current constitution (2005) was drafted by a council (some of whose members were not Iraqi) appointed by the United States and other forces occupying Iraq at the time (the 'Coalition Provisional Authority'). The constitution has been criticized by many Iraqis for emphasizing sectarian and ethnic identity over national unity.

Jordan

Jordan achieved independence from Britain in 1946, but English law is primarily influential in arbitration law. French law influenced Jordan's civil and commercial laws. Like many other states in the region, family law is based on Islamic legal traditions. Jordan's Constitution dates to 1952, but was amended in 1984. Civil and criminal matters are handled by regular courts (First Instance, Courts of Appeal, and Court of Cassation); religious courts (Islamic and Christian) handle personal status matters; there are also military and administrative courts (Haddad, 1994: p. 178). Jordan's 1953 land law permitted the transformation of state-owned land to private ownership in specific situations. A 2006 antiterrorism law expanded the jurisdiction of the Jordanian state security court (Haddad, 2005–2006: p. 290). In 2010–11, a number of legal reforms – including the establishment of a constitutional court – were enacted to heed off a potential uprising (Haddad, 2010–2011: p. 209).

Kuwait

Kuwait was under British control between 1914 and 1961, but its legal system is based on Ottoman and Islamic laws, rather than British common law. In 1962, Kuwait enacted a constitution that identifies Islam as the state religion. Kuwait's civil code is based on the Egyptian civil code (since it was drafted by the Egyptian jurist, Sanhūrī). Kuwaiti judges sometimes defer to Egyptian precedents (Kassim, 1994: p. 254). Kuwait promulgated several codes in 1960 (criminal, criminal procedure, and commercial companies), 1964 (commercial agencies and labor), and 1980 (commercial, civil and commercial procedures, and maritime commercial) (Kassim, 1994: p. 255). The judiciary includes the Court of First Instance, the Court of Appeals, and the Court of Cassation. Kuwait's civil code (1980) was intentionally designed to incorporate legal opinions from multiple Islamic legal schools. The only tax in Kuwait is applied to corporate income (Kassim, 1994: p. 271).

Lebanon

Lebanon was under French colonial rule from 1920 (when the Ottoman Empire dissolved) to 1943. Its legal system is primarily based on the French civil law system, beginning with the Code of Obligations and Contracts (1932). Civil, commercial, and criminal courts are overseen by the Court of Cassation, whereas the Conseil d'Etat oversees administrative law. Nearly 20 distinct confessional systems (Islamic and Christian sects, as well as Judaism) govern family law; however, inheritance is a matter of civil law, not subject to religious courts. Ten legal professionals sit on Lebanon's Constitutional Council, which was founded in 1989 (Mallat, 1994: pp. 204–205). The rule of law disintegrated during the Lebanese civil war (1975–90); in its aftermath, Lebanon promulgated several laws relating to property, taxation, and estates to deal with gaps and non-functionality in the existing laws (Mallat, 1994: pp. 214–217). Reflecting the implications of a prolonged and chaotic civil war, Lebanon passed a law in 1995 that declares as dead any individual who had gone missing for more than 4 years; this law was implemented to facilitate inheritance cases (Mallat, 1994: p. 217). The complexity of asserting the rule of law in Lebanon is evident in the uneven application of criminal proceedings against individuals who committed actionable crimes during the war; many individuals directly involved in warfare became part of the state's administration after the war (Mallat, 1994: p. 219).

Libya

Libya's civil legal system is based on the French and Egyptian civil codes. The first article of Libya's civil code identifies the state's legal sources as legislation, Islamic legal principles, custom, and natural law or equity (El-Alem, 1994: p. 225). Libya's judicial hierarchy includes a Supreme Court, appellate courts, and first instance courts (El-Alem, 1994: p. 226). The Libyan Constitution gives Basic Popular Conferences legislative authority (El-Alem, 1994: p. 227). Civil and commercial procedures are governed by a 1954 code; in 1994, popular tribunals, a new type of court, were introduced

(El-Alem, 1994: pp. 230–231). A 1992 property law gives every Libyan citizen the right to own property (El-Alem, 1994: p. 232). Various modifications related to polygyny laws occurred during the 1990s (El-Alem, 1994: p. 233). Libyan law (1974 and 1994) prohibits consumption, possession, and production of alcohol by Muslims, but non-Muslims have the right to consume alcohol in private (El-Alem, 1994: p. 235). In 1994, Libya passed an Arabic language act that requires all public materials to be in Arabic or include an Arabic translation of foreign languages (El-Alem, 1994: p. 236).

After the Libyan uprising of 2011, foreign intervention, and the removal of Colonel Qadhdhāfī (Gaddafi) and his government, a General National Council was formed in 2012 with the intention of writing a constitution for Libya. Libya's legal system is unstable and in transition.

Morocco

The Kingdom of Morocco gained independence from colonial rule in 1956. Morocco's Constitution (of 1996, preceded by revisions and constitutions in 1992, 1972, 1970, and 1962) identifies Islam as the official religion. The civil procedure code (1959), the penal code (1962), and other Moroccan codes are primarily influenced by French codes. The state's judicial hierarchy includes a Supreme Court, courts of appeal, and courts of first instance (Zirari-Devif, 1994: pp. 411–412). In 2002, laws against terrorism were enacted that significantly extended police powers (Zirari-Devif, 2002–2003: pp. 357–358). King Muhammad VI of Morocco requested a new personal status code (*muduwwanah*) that was adopted by parliament in 2003; the new code limited polygyny, gave previously unmarried women the authority to contract marriages without a guardian, and restricted men's abilities to divorce (Zirari-Devif, 2003–2004: pp. 285–288). The King of Morocco initiated a series of legal reforms in 2011 in order to prevent a popular uprising (Zirari-Devif, 2010–2011: p. 289).

Oman

The modern state of Oman was recognized as sovereign in 1951 and has been ruled by Sultan Qābūs as an absolute monarchy since 1971. Royal decrees are the primary source of legislation; Oman's commercial law (1990) is based on Kuwaiti, Egyptian, and French laws (Edmondes, 1994: p. 350). The dominant Islamic school of law is Ibāḍī. Oman established special security courts to deal with political threats against the state or Sultan in 2003 (Rae and Howard, 1994: p. 295).

Qatar

Qatar gained independence from Britain in 1971 and is an absolute monarchy. Qatar's 2003 constitution established an elected parliament and identified Islamic law as a source of legislation (Al Tamimi, 2005–2006: p. 375). As in many other MENA states, Egyptian laws influence Qatari law. The civil and Islamic courts, once separate, were recently united. The Council of Ministers drafts laws for consideration by the Consultative Council and the Cabinet (Al-Nauimi, 1994: p. 345).

Saudi Arabia

Saudi Arabia is an absolute monarchy, which means that the monarch has ultimate authority. Saudi rules of civil procedure were issued in 1936 and 1952; the Ministry of Justice was established in 1970 and it issues Islamic legal decrees on a variety of issues (Abrahams, 1994: pp. 275–276). In 1992, Saudi Arabia passed its Basic Law, which is modeled after a constitution, although the first article identifies the Qur'ān as the state's constitution (Mallat, 2007: p. 160). An 'Islamic' procedural law was enacted in 2000 and was the first systematization of legal procedures in the kingdom (Hejailan, 2000–2001: p. 271). A Supreme Court and a Supreme Judicial Council were both established in 2007 (Dahlan and Zedan, 2008–2009: p. 339). While in theory Islamic law is the main source of law, regional and international laws have been integrated into the Saudi legal system. Saudi courts do not publish court decisions; prior to the 1980s, however, the decisions of courts of equity were reported (Mallat, 1998: p. 118). Commercial regulations, often influenced by Egyptian or Western practices, are promulgated by the Council of Ministers (Abrahams, 1994: p. 274). Islamic courts hear cases involving family, criminal, property, and personal injury matters (Abrahams, 1994: p. 277). The Board of Grievances (established in 1955) deals with claims against the government (Abrahams, 1994: p. 278). Saudi business law has developed to deal with the large numbers of foreign investors and foreign professionals working in the country. While only citizens may be qualified to practice law, foreign attorneys often function as legal consultants to members of the Saudi bar.

Syria

Syria became independent from French colonial rule in 1946, at which time the state issued several legal codes that were modeled after Lebanese or Egyptian codes. Syria's 1973 Constitution gives the People's Assembly and the President shared legislative power (El-Hakim, 1994: pp. 142–143). Many commercial laws were enacted in the mid-twentieth century to encourage foreign investment, tourism, and banking operations. Syria's labor laws require employer-provided social insurance. Personal status matters are handled by Islamic and other confessional courts. Civil and criminal courts are subject to appeal. Syria has three lower criminal courts (police, first degree, and court of criminal appeal). The Superior Judicial Council appoints judges and oversees lower courts. The Higher Constitutional Court deals with the constitutionality of laws (El-Hakim, 1994: p. 153). In 2011, the Syrian government issued a new constitution making broad legal changes; it was 'approved' in 2012; the country is in the midst of a civil war (El-Hakim and Harding, 2010–2011: p. 179).

Sudan

Sudan's legal system combines English common law, Islamic law, and customary law. Britain established a system of dual courts in the country, with 'secular' courts handling civil and criminal matters and Islamic courts handling the family law matters of Muslims (Safwat, 1994: p. 237). Islamic law was

integrated into the operation of all courts through the Judicial Decision Sources Act (1983), Civil Procedure Act (1983), Evidence Act (1983), Civil Transactions Act (1984), and Penal Code (1991). Most of these laws also identified the importance of custom to Sudanese law (Safwat, 1994: p. 238). Sudan's judiciary includes a Supreme Court, courts of appeal, provincial courts, district courts, town benches, and other courts (Safwat, 1994: p. 239). A personal status code was issued in 1991 for Muslims, integrating legal opinions from the Ḥanafī and Mālikī schools (Safwat, 1994: p. 250). Some parts of the Sudanese penal code that were based on Islamic law were not applied in Southern Sudan (which became independent in 2011) (Safwat, 1994: p. 253). The 1990 National Security Act gives the government broad authority to detain citizens without formal charges. Sudan's 1998 constitution identified the state as Islamic, created a constitutional court, and made numerous other legal changes (Makec, 1997–1998: p. 308). A new constitution was adopted in 2005.

Tunisia

Tunisia achieved independence from France in 1956 and adopted a constitution in 1959 (Gaigi, 1994: p. 419). Initially applicable to Muslims only, the personal status code (1956) was extended to all Tunisian citizens in 1957 (Gaigi, 1994: p. 420). The Tunisian legal system includes several codes, including civil and commercial procedure (1959), commercial (1959), and criminal procedure (1968, revised 1993) (Gaigi, 1994: p. 420). Tunisia's personal status code (1956), which has been revised repeatedly, is based on Islamic law with many modifications; it has been the subject of extensive analysis and commentary (Gaigi, 1994: p. 423). The Tunisian uprising began in 2010 and the Tunisian Constituent Assembly recently issued a new constitution.

Turkey

Turkey became a republic in 1923; in 1926, the state adopted the Swiss Civil Code (replacing the Ottoman civil code), when it was approved by the Grand National Assembly, after years of lobbying by Atatürk (Mallat, 1998: p. 114). Turkey's penal code (1926), civil procedure code (1927), and criminal procedure code (1929) were all modeled after European codes (Dogru, 1995: p. 285). Turkey's current constitution (1982, amendments through 2008) replaced several earlier constitutions and was ratified under a military government that came to power by a *coup d'état* in 1980; the Constitutional Court reviews the constitutionality of laws passed by parliament after military rule ended in 1983 (Dogru, 1995: p. 287). Turkey's constitution does not identify Islamic law as a source of law.

United Arab Emirates

The United Arab Emirates (UAE) was established as a federation of seven emirates in 1971–72 and has a Supreme Council that is responsible for approving laws and international agreements; essentially, it has a form of monarchical governance. While its constitution identifies Islamic law as the principal source of law, Egyptian codes, English common law, and local customs are influential (Price, 1994: p. 303). The Council of Ministers drafts laws that are then sent, in succession, to the National Assembly and the Supreme Council for approval (Price, 1994: p. 305). Civil (1987), penal (1987), and commercial (1993) codes demarcate much of the daily operation of law in the UAE. The UAE's civil code incorporates a few Islamic legal principles that were cited in the Ottoman civil code (Price, 1994: p. 305). The judicial hierarchy includes the Court of Cassation, the Court of Appeal, the Court of First Instance, as well as criminal and Islamic courts (Price, 1994: p. 304). In terms of the application of Islamic law, UAE courts give more legal weight to the opinions of the Mālikī and Ḥanbalī schools (Price, 1994: p. 303). Although only citizens may be qualified to practice law, foreign attorneys often function as legal consultants to members of the UAE bar. In 1994, the UAE promulgated an extensive Commercial Code; as a member of the Arab Gulf Corporation Council (founded in 1981), the UAE enacts economic laws that are in line with the regional goals of Arab Gulf States (Price, 1994: p. 305).

Yemen

The modern republic of Yemen was created with the unification of North and South Yemen in 1990. Yemen's 1994 Constitution identifies Islamic law as the primary source of law; Yemen's civil code elaborates that Islamic law, customary practices, and principles of equity are the main sources of law (Shamiri, 1994: p. 369). Laws are promulgated by the parliament, executive decrees, and resolutions of various ministers, all of which are published in Yemen's official legal journal (Shamiri, 1994: p. 370). Yemen's judicial hierarchy includes a Supreme Court, a court of appeal, and a court of first instance (Shamiri, 1994: pp. 371–372). The Yemeni Civil Code (1992) codifies many Islamic legal principles (Shamiri, 1994: p. 378). Personal status matters and criminal punishments are governed by Islamic law. In 1997, Yemen initiated a judicial reform program and established a government institution for issuing Islamic legal decrees (*dār al-iftā'*) (Shamiri, 1997–1998: pp. 390–395). Yemen established a national security organization to deal with political threats against the state in 2003 (Shamiri, 2002–2003: pp. 315–317). The Yemeni uprising began in 2011 and it is unclear what legal changes will emerge as a result of this ongoing political transformation.

Conclusion

The modern history of the MENA is characterized by recurring shifts between direct colonial occupation and indirect imperialist interventions. The complexity of this ongoing imperial situation shapes the rule of law and provokes the contours of legal debates that superficially (and incorrectly) pit tradition against modernity, religion against secularism, Islamic law against national legal systems; what underlies these debates is not a struggle between these false bipolarities, but a battle for autonomy, cultural dignity, and popular representation. Internal disputes about law in the MENA region reflect broader

controversies over the distribution of power, economic resources, and social capital. As the region continues to be embroiled in uprisings (Tunisia, Egypt, Syria, Yemen, and Bahrain), military coups (most recently in Egypt in 2013), foreign interventions, and general instability, law functions inconsistently and unpredictably.

Abstract

Middle adulthood is an important developmental period in the life span. The goal of this article is to give an overview about theoretical and empirical work on midlife development. The first part emphasizes the importance of studying midlife development. The second part presents conceptual frameworks and central issues of midlife. The third part summarizes research findings for environmental changes in the primary social contexts and social roles of midlife including family, work, and community. The fourth part summarizes research findings for individual changes in multiple domains such as cognitive and emotional abilities, personality and the self. The final part includes future directions.

Middle Adulthood
